Abstract

We present a lightweight approach to Hoare-style specifications for fine-grained concurrency, based on a notion of *time-stamped histories* that abstractly capture atomic changes in the program state. Our key observation is that histories form a *partial commutative monoid*, a structure fundamental for representation of concurrent resources. This insight provides us with a unifying mechanism that allows us to treat histories just like heaps in separation logic. For example, both are subject to the same assertion logic and inference rules (e.g., the frame rule). Moreover, the notion of ownership transfer, which usually applies to heaps, has an equivalent in histories. It can be used to formally represent helping—an important design pattern for concurrent algorithms whereby one thread can execute code on behalf of another. Specifications in terms of histories naturally abstract granularity, in the sense that sophisticated fine-grained algorithms can be given the same specifications as their simplified coarse-grained counterparts, making them equally convenient for client-side reasoning. We illustrate our approach on a number of examples and validate all of them in Coq.

1. Introduction

For sequential programs and data structures, Hoare-style specifications (or specs) in the form of pre- and postconditions are a declarative way to express a program's behavior. For example, an abstract specification of stack operations can be given as follows:

$$\begin{aligned} & \{ s \mapsto xs \} \text{push}(x) \{ s \mapsto x :: xs \} \\ & \{ s \mapsto xs \} \text{pop}() \left\{ \begin{array}{l} \text{res} = \text{None} \wedge xs = \text{nil} \wedge s \mapsto \text{nil} \vee \\ \text{res} = \text{Some } x \wedge \exists xs', xs = x :: xs' \wedge s \mapsto xs' \end{array} \right\} \end{aligned} \quad (1)$$

where s is an “abstract pointer” to the data structure's logical contents, and the logical variable xs is universally quantified over the spec. The result res of pop is either $\text{Some } x$, if x was on the top of the stack, or None if the stack was empty. The spec (1) is usually accepted as canonical for stacks: it hides the details of method implementation, but exposes what's important about the method behavior, so that a verification of a stack *client* doesn't need to explore the implementations of push and pop .

The situation is much more complicated in the case of concurrent data structures. In the concurrent setting, (1) is of little use, as the interference of the threads executing concurrently may invalidate the assertions about the stack. For example, a call to pop may encounter an empty stack, and decide to return None , but by the time it returns, the stack may be filled by the other threads, thus invalidating the postcondition of pop in (1). To soundly reason about concurrent data structures, one has to devise specs that are *stable* (i.e., invariant under interference), but this may require trade-offs.

For instance, a few recent proposals [28, 30] rely on the following spec, which restricts the stack elements to satisfy a fixed client-chosen predicate P :

$$\begin{aligned} & \{ P(x) \} \text{push}(x) \{ \text{true} \} \\ & \{ \text{true} \} \text{pop}() \{ \text{res} = \text{Some } x \implies P(x) \} \end{aligned} \quad (2)$$

Specification (2) is stable, but it isn't canonical, as it doesn't capture the LIFO element management policy. It holds of any other container structure, such as queues.

Reasoning about concurrent data structures is further complicated by the fact that their implementations are often *fine-grained*. Striving for better performance, they avoid explicit locking, and implement sophisticated synchronization patterns that deliberately rely on interference. For reasoning purposes, however, it is desirable that the clients can perceive such fine-grained implementations as if they were *coarse-grained*; that is, as if the effects of their methods take place *atomically*, at singular points in time. The standard correctness criteria of *linearizability* [16] establishes that a fine-grained data structure implementation *contextually refines* a coarse-grained one [9]. One can make use of a refined, fine-grained, implementation for efficiency in programming, but then soundly replace it with a more abstract coarse-grained implementation, to simplify the reasoning about clients.

Semantically, one program linearizes to another if the *histories* of the first program (i.e., the sequence of actions it executed) can be transformed, in a suitable sense, into the histories of the second. Thus, histories are an essential ingredient in specifying fine-grained concurrent data structures. However, while a number of logical methods exist for establishing the linearizability relation between two programs, for a class of structures [6, 20, 24, 32, 34], in general, it's a non-trivial property to prove and use. First, in a setting that employs Hoare-style reasoning, showing that a fine-grained structure refines a coarse-grained one is not an end in itself. One still needs to ascribe a stable spec to the coarse-grained version [20, 30]. Second, the standard notion of linearizability doesn't directly account for modern programming features, such as ownership transfer of state between threads, pointer aliasing, and higher-order procedures. Theoretical extensions required to support these features are a subject of active ongoing research [3, 11]. Finally, being a relation on *two* programs, deriving linearizability by means of logical inference inherently requires a *relational program logic* [20, 30], even though the spec one is ultimately interested in (e.g., (2) for a concurrent stack) may be expressed using a Hoare triple that operates over a *single* program.

In this paper, we propose a novel method to specify and verify fine-grained programs *as well as* provide a form of granularity abstraction, by directly reasoning about histories in the specs of an elementary Hoare logic. We propose using *timestamped* histories, which carry information about the atomic changes in the abstract state of the program, indexed by discrete time stamps, and tracking the history of a program as a form of auxiliary state.

Histories can help abstract the granularity of a program as follows. We consider a program *logically* atomic (irrespective of the physical granularity of its implementation), if its history is a singleton history $t \mapsto a$, containing only an abstract action a time-stamped with t . This spec provides an abstraction that the effect a of the program takes place at a singular point in time t , as if the program were coarse-grained, thus achieving exactly the main goal of

linearizability, without needing contextual refinement. Client-side proofs can be developed out of such a spec, while ignoring the details of a potentially fine-grained implementation. The user can select the desired level of granularity, by choosing the actions a to use in the histories. While using histories in Hoare logic specs is a simple and natural idea, and has been employed before [10, 12], in our paper it comes with two additional novel observations.

First, timestamped histories are technically very similar to heaps, as both satisfy the algebraic properties of a *partial commutative monoid* (PCM). A PCM is a set \mathbb{U} with an associative and commutative *join* operation \bullet and unit element $\mathbb{1}$. Both heaps and histories form a PCM with disjoint union and empty heap/history as the unit. Also, a singleton history $t \mapsto a$ is very similar to the singleton heap $x \mapsto v$ containing only the pointer x with value v . We emphasize the connection by using the same notation for both.

The common PCM structure makes it possible to reuse for histories the ideas and results developed for heaps in the work on separation logic [2]. In particular, in this paper, we make both heaps and histories subject to the same assertion logic and the same rules of inference (e.g., the frame rule). Moreover, concepts such as ownership transfer, that have been developed for heaps, apply to histories as well. For example, in Section 5, we use ownership transfer on histories to formalize the important design pattern of *helping* [14], whereby a concurrent thread may execute a task on behalf of other threads. That helping corresponds to a kind of ownership transfer (though not on histories, but on auxiliary commands) has been noticed before [20, 31]. However, commands don't form a PCM, while histories do – a fact that makes our development simple and uniform.

Second, we argue that precise history-based specs have to differentiate between the actions that have been performed by the specified thread, from the actions that have been performed by the thread's concurrent environment. Thus, our specs will range over *two* different history-typed variables, capturing the timestamped actions of the specified thread (*self*) and its environment (*other*), respectively. This split between self and other will provide us with a novel and very direct way of relating the functional behavior of a program to the interference of its concurrent environment, leading to specs that have a similar canonical “feel” in the concurrent setting, as the specs (1) have in the sequential one.

The self/other dichotomy required of histories is a special case of the more general specification pattern of *subjectivity*, observed in the recent related work on Subjective and Fine-grained Concurrent Separation Logic (FCSL) [19, 22]. That work generalized Concurrent Separation Logic (CSL) [23] to apply not only to heaps, but to any abstract notion of state (real or auxiliary) satisfying the PCM properties. We thus reuse FCSL [22] off-the-shelf, and instantiate it with histories, *without any additions to the logic or its meta-theory*. Surprisingly, the FCSL style of auxiliary state is sufficient to enable expressive history-based, granularity-abstracting specs, and proofs of realistic fine-grained algorithms, including those with helping. We show how a number of well-known algorithms can be proved logically atomic, and illustrate how the atomic specs facilitate client-side reasoning. We consider an atomic pair snapshot data structure [20, 26] (Section 2), Treiber stack [29] along with its clients (Section 4), and Hendler *et al.*'s flat combining algorithm [14], a highly non-trivial example employing higher-order functions and helping (Section 5). All our proofs, including the theory of histories, have been checked mechanically in Coq.¹

2. Overview: specifying snapshots with histories

In this section, we illustrate history-based specifications by applying them to the fine-grained *atomic pair snapshot* data structure

```

1 readPair():  $A \times A$  {
2   (cx, vx) <- readX();
3   (cy, vy) <- readY();
4   (tx, tx) <- readX();
5   if vx == tx
6   then return (cx, cy);
7   else return readPair();

```

Figure 1. Main method of the atomic pair snapshot data structure.

[20, 26]. This data structure contains a pair of pointers, x and y , pointing to tuples (c_x, v_x) and (c_y, v_y) , respectively. The components c_x and c_y of type A represent the accessible contents of x and y , that may be read and updated by the client. The components v_x and v_y are nats, encoding “version numbers” for x and y . They are internal to the structure and not directly accessible by the client.

The structure exports three methods: `readPair`, `writeX`, and `writeY`. `readPair` is the main method, and the focus of the section. It returns the *snapshot* of the data structure, i.e., the accessible contents of x and y as they appear together at the moment of the call. However, while x and y are being read by `readPair`, other threads may change them, by invoking `writeX` or `writeY`. Thus, a naïve implementation of `readPair` which first reads x , then y , and returns the pair (c_x, c_y) does not guarantee that c_x and c_y ever appeared together in the structure. One may have `readPair` first lock x and y to ensure exclusive access, but here we consider a fine-grained implementation which relies on the version numbers to ensure that `readPair` returns a valid snapshot.

The idea is that `writeX(cx)` (and symmetrically, `writeY(cy)`), changes the logical contents of x to cx , while incrementing the internal version number, *simultaneously*. Since the operation involves changes to the contents of a single pointer, in this paper we assume that it can be performed atomically (e.g., by some kind of read-modify-write operation [15, §5.6]). We also assume atomic operations `readX` and `readY` for reading from x and y respectively. Then the implementation of `readPair` (Figure 1) reads from x and y in succession, but makes a check (line 5) to compare the version numbers for x obtained before and after the read of y . In case x 's version has changed, the procedure is restarted.

We want to specify and prove that such an implementation of `readPair` is correct; that is, if it returns a pair (c_x, c_y) , then c_x and c_y occurred simultaneously in the structure. To do so, we use histories as auxiliary state of every method of the structure. Histories, ranged over by τ , are finite maps from the natural numbers to pairs of elements of some type S ; i.e., $\text{hist } S \triangleq \text{nat} \rightarrow S \times S$. The natural numbers represent the moments in time, and the pairs represent the change of state. Thus, a singleton history $t \mapsto (s_1, s_2)$ encodes an atomic change from abstract state s_1 to abstract state s_2 at the time moment t . We will only consider *continuous* histories, for which $t \mapsto (s_1, s_2)$ and $t + 1 \mapsto (s_3, s_4)$ implies $s_2 = s_3$. We use the following abbreviations to work with histories:

$$\begin{aligned}
\tau[t] &\triangleq s, \text{ such that } \exists s', \tau(t) = (s', s) \\
\tau \leq t &\triangleq \forall t' \in \text{dom}(\tau), t' \leq t \\
\tau \sqsubseteq \tau' &\triangleq \tau \text{ is a subset of } \tau'
\end{aligned} \tag{3}$$

Similarly to heaps, histories form a PCM under the operation \cup of disjoint union, with the empty history as the unit. The type S can be chosen arbitrarily, depending on the application, to capture whichever logical aspects of the actual physical state are of interest. For the snapshot structure, we take $S = A \times A \times \text{nat}$. That is, the entries in the histories for pair snapshot will be of the form

$$t \mapsto (\langle c_x, c_y, v_x \rangle, \langle c'_x, c'_y, v'_x \rangle). \tag{4}$$

The entry encodes that at time moment t , the contents of x , y , and the version of x have changed from (c_x, c_y, v_x) to (c'_x, c'_y, v'_x) . We ignore v_y , as it doesn't factor in the implementation of `readPair`.

¹ Available at <http://ilyasergey.net/other/fcsl-histories.zip>.

All the threads working over the pair snapshot structure respect a protocol on histories consisting of the following three properties. We explain in Section 3 how these are formally specified and enforced, but for now simply assume them. They will be important in the proof outline for `readPair`.

- (i) Whenever a thread modifies x or y (e.g., by calling `writeX` or `writeY`), its history gets augmented by an entry such as (4), where the timestamp t is chosen afresh. Thus, histories only grow, and only by adding valid snapshots.
- (ii) Whenever the contents of x is changed in a history, its version number changes too. In contrapositive form, if $\tau[t_1] = \langle c_1, -, v \rangle$ and $\tau[t_2] = \langle c_2, -, v \rangle$, then $c_1 = c_2$.
- (iii) Version numbers in a history grow monotonically. That is, if $\tau[t_1] = \langle -, -, v_1 \rangle$ and $\tau[t_2] = \langle -, -, v_2 \rangle$ and $t_1 \leq t_2$, then $v_1 \leq v_2$.

Specification. We now describe an FCSL spec for `readPair` and explain how it captures that its result is a valid snapshot of x and y .

$$\begin{aligned} & \left\{ \exists \tau_0. \ell \xrightarrow{s} \text{empty} \wedge \ell \xrightarrow{o} \tau_0 \wedge \tau \sqsubseteq \tau_0 \right\} \\ & \text{readPair}() \\ & \left\{ \exists \tau_0. t. \ell \xrightarrow{s} \text{empty} \wedge \ell \xrightarrow{o} \tau_0 \wedge \tau \sqsubseteq \tau_0 \wedge \right. \\ & \quad \left. \tau \leq t \wedge \tau_0[t] = \langle \text{res.1}, \text{res.2}, - \rangle \right\} \end{aligned} \quad (5)$$

First, note the label ℓ , which serves as an “abstract pointer” that differentiates the instance of the pair snapshot structure from any other structure that may exist in the program. In particular, ℓ identifies the histories of concern to `readPair`. Each thread keeps track of two such histories: the self-history, describing the operations that the thread itself has executed, and the other-history, describing the operations executed by all the other threads combined. They are captured by the assertions $\ell \xrightarrow{s} \tau$ and $\ell \xrightarrow{o} \tau$, respectively.

Thus, the precondition in (5) requires that `readPair` starts with the empty self-history, i.e., the calling thread has not performed any updates to x or y . We show in Section 3 that the frame rule can be used to relax the requirement, so that `readPair` can be invoked by threads with an arbitrary self history. The precondition allows an arbitrary initial other-history τ_0 . As τ_0 is bound locally in the precondition, and we need to relate to it in the postcondition, we use the logical variable τ , and a conjunct $\tau \sqsubseteq \tau_0$ to “name” it. The conjunct uses inclusion (instead of equality). Inclusion makes the precondition stable under growth of τ_0 due to interfering threads, according to (i).

The postcondition states that `readPair` does not perform any changes to x and y ; it’s a *pure* method, thus its self-history remains empty. The main novelty of the specification is that the postcondition directly relates the result of `readPair` to the interference of the environment, i.e., to the value of τ_0 . Referring to τ_0 may look odd at first, but it’s appropriate, and precisely specifies what `readPair` returns. In particular, the postcondition says that $\tau_0[t] = \langle \text{res.1}, \text{res.2}, - \rangle$, i.e., that the components of the returned pair `res` appear in the environment history. Since according to the property (i) above, the histories only store valid snapshots, the resulting pair must be a valid snapshot too. In other words, `readPair` behaves as if it read x and y atomically, at time t . Moreover, $\tau \leq t$, i.e., the read occurred after `readPair` was invoked.

The specification pattern whereby a logical variable τ names the initial history of the environment is very common, so we streamline it by introducing the following notation.

$$\ell \hookrightarrow (\tau_S, \tau_O, \tau) \triangleq \ell \xrightarrow{s} \tau_S \wedge \ell \xrightarrow{o} \tau_O \wedge \tau \sqsubseteq \tau_S \cup \tau_O \quad (6)$$

Proof outline. Figure 2 contains the proof outline for `readPair`, which we discuss next. Lines 1 and 3 abbreviate the precondition in (5). The `readX` method has the following spec:

$$\left\{ \ell \hookrightarrow (\text{empty}, -, \tau) \right\} \text{readX}() \left\{ \exists \tau_0. t. \ell \hookrightarrow (\text{empty}, \tau_0, \tau) \wedge \tau \leq t \wedge \tau_0[t] = \langle \text{res.1}, -, \text{res.2} \rangle \right\} \quad (7)$$

```

1 { ℓ ↦ (empty, -, τ) }
2 readPair(): A × A {
3 { ℓ ↦ (empty, -, τ) }
4 (cx, vx) <- readX();
5 { ℓ ↦ (empty, τ1, τ) ∧ τ ≤ t1 ∧ τ1[t1] = ⟨cx, -, vx⟩ }
6 (cy, -) <- readY();
7 { ℓ ↦ (empty, τ2, τ) ∧ τ ≤ t1 ≤ t2 ∧ vx ≤ v ∧
  { τ2[t1] = ⟨cx, -, vx⟩ ∧ τ2[t2] = ⟨c, cy, v⟩ }
8 (-, tx) <- readX();
9 { ℓ ↦ (empty, τ3, τ) ∧ τ ≤ t1 ≤ t2 ≤ t3 ∧ vx ≤ v ≤ tx ∧
  { τ3[t1] = ⟨cx, -, vx⟩ ∧ τ3[t2] = ⟨c, cy, v⟩ ∧ τ3[t3] = ⟨-, -, tx⟩ }
10 if vx == tx
11 { ℓ ↦ (empty, τ3, τ) ∧ τ ≤ t2 ∧ cx = c ∧ τ3[t2] = ⟨cx, cy, v⟩ }
12 then return (cx, cy);
13 { ∃τ0. t. ℓ ↦ (empty, τ0, τ) ∧ τ ≤ t ∧ τ0[t] = ⟨res.1, res.2, -⟩ }
14 else return readPair(); }
15 { ∃τ0. t. ℓ ↦ (empty, τ0, τ) ∧ τ ≤ t ∧ τ0[t] = ⟨res.1, res.2, -⟩ }

```

Figure 2. Proof outline for `readPair`. Note that $\tau \sqsubseteq \tau_0$ is folded into the definition of $\ell \hookrightarrow (\text{empty}, \tau_0, \tau)$.

Thus in line 5 of the proof outline, we infer the existence of the history τ_1 and time stamp $t_1 \geq \tau$, such that the `cx` and `vx` appear in τ_1 at the time t_1 . Similarly, `readY` has the spec:

$$\left\{ \ell \hookrightarrow (\text{empty}, -, \tau) \right\} \text{readY}() \left\{ \exists \tau_0. t. \ell \hookrightarrow (\text{empty}, \tau_0, \tau) \wedge \tau \leq t \wedge \tau_0[t] = \langle -, \text{res.1}, - \rangle \right\} \quad (8)$$

To obtain line 7, instantiate τ with τ_1 in the spec of `readY`. This derives the existence of τ_2 , t_2 , c and v , such that $\ell \hookrightarrow (\text{empty}, \tau_2, \tau_1)$, $\tau_1 \leq t_2$, and $\tau_2[t_2] = \langle c, cy, v \rangle$. Because $t_1 \in \text{dom}(\tau_1)$, it must be that $t_1 \leq t_2$. Moreover, because $\tau \sqsubseteq \tau_1 \sqsubseteq \tau_2$, we further obtain $\ell \hookrightarrow (\text{empty}, \tau_2, \tau)$, and $\tau \leq t_2$, and lifting from line 5, $\tau_2[t_1] = \langle cx, -, vx \rangle$. Because t_1, t_2 appear in the same history τ_2 , with versions `vx` and v , respectively, by property (iii), $vx \leq v$. Similarly, instantiating τ in the spec of `readX` with τ_2 , and invoking (iii), derives line 9 of the proof outline, and in particular $vx \leq v \leq tx$.

From this property, if $vx = tx$ in the conditional on line 10, it must be that $vx = v$, and thus by (ii), $cx = c$. Substituting c by `cx` in line 9 gives us $\tau_3[t_2] = \langle cx, cy, v \rangle$, which, after (cx, cy) are returned in `res`, obtains the postcondition of `readPair`. Otherwise, if $vx \neq tx$ in the conditional 10, we perform the recursive call to `readPair`. The precondition for the call is $\ell \hookrightarrow (\text{empty}, -, \tau)$, which is clearly met in line 9, so the postcondition immediately follows.

Monolithic histories. We compare the spec (5) with an alternative spec where the history is not split into self/other portions, but is kept monolithically as a *joint* (or shared) state. We use the predicate $\ell \xrightarrow{j} \tau$ to specify such state:

$$\begin{aligned} & \left\{ \exists \tau_0. \ell \xrightarrow{j} \tau_0 \wedge \tau \sqsubseteq \tau_0 \right\} \\ & \text{readPair}() \\ & \left\{ \exists \tau_0. t. \ell \xrightarrow{j} \tau_0 \wedge \tau \sqsubseteq \tau_0 \wedge \tau \leq t \wedge \tau_0[t] = \langle \text{res.1}, \text{res.2}, - \rangle \right\} \end{aligned} \quad (9)$$

Note that the spec (9) imposes no restrictions on the growth of τ_0 (unlike (5) which keeps the self history empty). Thus, (9) is weaker than (5), as it allows more behaviors. In particular, it can be ascribed to any program which, in addition to calling `readPair`, also modifies x and y . This substantiates our claim from Section 1 that the self/other dichotomy is required to prevent history-based specs from losing precision. We provide further evidence for this claim in Section 4, where we show that subjective specs for *stacks* generalize the sequential canonical ones (1). The latter can be derived from the former by restricting τ_0 to be the empty history. Such a restriction isn’t possible if the history is kept monolithic.

3. Background: a review of FCSL

In this section we review the relevant aspects of the previous work on Fine-grained Concurrent Separation Logic (FCSL) [22]. We explain FCSL by showing how it can be specialized to our novel contribution of specifying concurrent objects by means of histories. FCSL has been previously implemented as a shallow embedding in Coq; thus our assertions will freely use Coq’s higher-order logic and datatype definition mechanism whenever required.

FCSL is a Hoare logic, generalizing CSL, hence its assertions are predicates on state. But unlike in CSL where state is a heap, in FCSL state may consist of a number of labeled components, each of which may represent state by a different type. If the type used by some label is non-heap, then that label encodes auxiliary state, used for logical specification, but erased at run time. For example, histories are an auxiliary state identified by the label ℓ in the atomic snapshot example. If we had a program which used two different atomic snapshot structures, we may label these by ℓ_1 and ℓ_2 , etc.

3.1 Subjectivity

The state recorded in labels is further divided across another orthogonal axis – ownership. Each label identifies three different chunks of state: self, joint and other portion. The self portion is private to the specified thread, and can’t be accessed by the other threads. Dually, other is private to the environment threads, and can’t be accessed by the one being specified. Finally, the joint section is shared and can be accessed by everyone. The self and other portions of any given label have to belong to a common PCM, and are often combined together by means of the \bullet operation of that PCM. Of course, different labels can use different PCMs.

The FCSL assertions reflect the division across these axes. We have already illustrated the assertions $\ell \xrightarrow{s} v$, $\ell \xrightarrow{j} v$ and $\ell \xrightarrow{o} v$, which identify the self/joint/other component stored in the label ℓ of the state. These three basic assertions can be combined by the usual propositional connectives, such as \wedge and \vee , as we have already shown in Section 2. FCSL further provides two connectives that generalize the *separating conjunction* $*$ from separation logic, along the two axes of state splitting. We next illustrate the *subjective separating conjunction* \otimes , and defer the discussion of the *resource separating conjunction* \circledast until additional technical material has been introduced. The formal definitions of all the connectives can be found in Appendix A.

The subjective conjunction \otimes is used to model the division of state between concurrent threads upon forking and joining. In particular, the parallel composition rule of FCSL is:

$$\frac{\{p_1\} c_1 \{q_1\} @ \mathcal{U} \quad \{p_2\} c_2 \{q_2\} @ \mathcal{U}}{\{p_1 \otimes p_2\} c_1 \parallel c_2 \{q_1 \otimes q_2\} @ \mathcal{U}} \quad (10)$$

Ignoring \mathcal{U} and the result types of c_1 and c_2 for now, we describe how \otimes works. In this rule, it splits the pre-state of $c_1 \parallel c_2$ into two parts, satisfying p_1 and p_2 respectively. The parts contain the same labels, and equal joint portions, but the self and other portions are recombined to match the thread-relative views of c_1 and c_2 . Concretely, in the case of one label ℓ , with a PCM \mathbb{U} and values $a, b, c \in \mathbb{U}$, we have the following illustrative implication.

$$\ell \xrightarrow{s} a \bullet b \wedge \ell \xrightarrow{o} c \implies (\ell \xrightarrow{s} a \wedge \ell \xrightarrow{j} b \bullet c) \otimes (\ell \xrightarrow{s} b \wedge \ell \xrightarrow{o} a \bullet c) \quad (11)$$

Thus, if before the fork, the self-state of the parent thread contained $a \bullet b$, and the other-state contained c , then after the fork, the children will have self-states a and b , and the other-states $b \bullet c$ and $a \bullet c$, respectively. In the opposite direction:

$$(\ell \xrightarrow{s} a \wedge \ell \xrightarrow{o} c_1) \otimes (\ell \xrightarrow{s} b \wedge \ell \xrightarrow{o} c_2) \implies \exists c. c_1 = b \bullet c \wedge c_2 = a \bullet c \wedge \ell \xrightarrow{s} a \bullet b \wedge \ell \xrightarrow{o} c \quad (12)$$

That is, if the state can be subjectively split between two child threads so that their other-views are c_1 , c_2 (with self-views a ,

b), then there exists a common c —the other-view of the parent thread—such that $c_1 = b \bullet c$ and $c_2 = a \bullet c$. In this sense, the rule for parallel composition models the important effect that upon a split, c_1 becomes an environment thread for c_2 , and vice-versa.

There are a few further equations that illustrate the interaction between the different assertions. First, every label contains all three of the self/joint/other components. Thus:

$$\ell \xrightarrow{s} a \iff \ell \xrightarrow{s} a \wedge \ell \xrightarrow{j} - \wedge \ell \xrightarrow{o} - \quad (13)$$

and similarly for $\ell \xrightarrow{j} a$ and $\ell \xrightarrow{o} a$. Also:

$$\ell \xrightarrow{s} a \bullet b \iff \ell \xrightarrow{s} a \otimes \ell \xrightarrow{s} b \quad (14)$$

which is provable from (11), (12) and (13).

FCSL also provides a *frame rule*, obtained as a special case of parallel composition when c_2 is the idle thread, and $p_2 = q_2 = r$ is a stable predicate, as usual in fine-grained logics [5, 7, 32].

$$\frac{\{p\} c \{q\} @ \mathcal{U} \quad r \text{ stable under } \mathcal{U}}{\{p \otimes r\} c \{q \otimes r\} @ \mathcal{U}} \quad (15)$$

We illustrate the frame rule by deriving from the readPair spec (5) a relaxed spec which allows readPair to apply when the calling thread has non-trivial self history τ_s :

$$\{ \ell \hookrightarrow (\tau_s, -, \tau) \} \text{readPair}() \left\{ \begin{array}{l} \exists \tau_0. t. \ell \hookrightarrow (\tau_s, \tau_0, \tau) \wedge \tau \leq t \wedge \\ (\tau_s \cup \tau_0)[t] = \langle \text{res.1}, \text{res.2}, - \rangle \end{array} \right\} \quad (16)$$

Note that (16), when compared to (5), changes the self component from empty to τ_s , but also $\tau_0[t]$ changes into $(\tau_s \cup \tau_0)[t]$. The latter accounts for the possibility that the returned snapshot may have been recorded in τ_s as a consequence of the thread itself changing x or y , immediately before invoking readPair.

The spec (16) derives from (5) by framing with the predicate $r = \ell \xrightarrow{s} \tau_s$. r is trivially stable, as it describes self-state, which is inaccessible to the interfering threads. We only show how to weaken the framed postcondition of (5) to the postcondition in (16); the preconditions can be strengthened similarly. Abbreviating $\tau \sqsubseteq \tau_0 \wedge \tau \leq t \wedge \tau_0[t] = \langle \text{res.1}, \text{res.2}, - \rangle$ by $P(\tau_0)$, which is a label-free (i.e. pure) assertion, and thus commutes with \otimes , we get:

$$\begin{aligned} (\ell \xrightarrow{s} \text{empty} \wedge \ell \xrightarrow{o} \tau_0 \wedge P(\tau_0)) \otimes (\ell \xrightarrow{s} \tau_s) &\implies \text{by (13) and } P\text{-pure} \\ (\ell \xrightarrow{s} \text{empty} \wedge \ell \xrightarrow{o} \tau_0) \otimes (\ell \xrightarrow{s} \tau_s \wedge \ell \xrightarrow{o} -) \wedge P(\tau_0) &\implies \text{by (12)} \\ \exists \tau'_0. \tau_0 = \tau_s \cup \tau'_0 \wedge \ell \xrightarrow{s} \tau_s \wedge \ell \xrightarrow{o} \tau'_0 \wedge P(\tau_0) &\implies \text{by substituting } \tau_0 \\ \exists \tau'_0. \ell \hookrightarrow (\tau_s, \tau'_0, \tau) \wedge \tau \leq t \wedge (\tau_s \cup \tau'_0)[t] = \langle \text{res.1}, \text{res.2}, - \rangle. \end{aligned}$$

Intuitively, the frame history τ_s is “subtracted” from the other-history τ_0 of (5), and moved to the self-history in (16). This illustrates one important difference between the frame rule of FCSL and that of CSL. In FCSL, the frame is always subtracted from the other component, whereas in CSL the frame simply materializes out of nowhere. On the flip side, CSL doesn’t consider the other component, and can’t easily express a spec such as (5).

3.2 Concurroids

We now turn to the component \mathcal{U} of the FCSL specs, which is called *concurroid*. Concurroids are responsible for enforcing the invariants on the evolution of the state. For example, the properties (i)–(iii) in Section 2 will be enforced by defining an appropriate concurroid to govern the pair-snapshot structure. Thus, concurroids formally represent concurrent data structures, over which the programs operate.

A concurroid is (a form of) a state transition system (STS). It’s a quadruple $\mathcal{U} = (L, W, I, E)$ where: (1) L is a set of labels, identifying different data structures; (2) W is a set of admissible states (alternatively, an FCSL assertion); (3) I is the set of *internal transitions* on W ; (4) E is a set of pairs (α, ρ) , where α is a *heap-acquiring* and ρ is a *heap-releasing* transition, collectively called *external transitions*. The internal transitions are relations on states,

describing how a state of the STS evolves in one atomic step. The external transitions serve for transfer of state ownership. The concurroids thus bound the moves of the concurrent programs that operate on a data structure, and therefore represent a structured form of rely/guarantee transitions from Rely/Guarantee logics [7, 8, 18, 32, 33]. We next illustrate concurroids by example.

Pair-snapshot concurroid. Given a label ℓ , pointers x, y , and the type A of the accessible contents of x and y , the concurroid for the pair-snapshot structure is $\mathcal{S} = (\{\ell\}, W_{\mathcal{S}}, \{wr_x, wr_y, id\}, \emptyset)$. The set of states $W_{\mathcal{S}}$ is described below. We assume that τ_s, τ_o are histories, $c_x, c_y : A$ and $v_x, v_y : \text{nat}$, and are implicitly existentially quantified.

$$W_{\mathcal{S}} \triangleq \ell \xrightarrow{s} \tau_s \wedge \ell \xrightarrow{j} (x \mapsto (c_x, v_x) \cup y \mapsto (c_y, v_y)) \wedge \ell \xrightarrow{o} \tau_o \wedge \\ \tau_s, \tau_o \text{ satisfy (ii) – (iii), } \tau_s \cup \tau_o \text{ is continuous, and} \\ \text{if } t = \text{last}(\tau_s \cup \tau_o), \text{ then } (\tau_s \cup \tau_o)[t] = (c_x, c_y, v_x)$$

A state in $W_{\mathcal{S}}$ consists of the auxiliary part, which are histories in the self and other components, and concrete part, which is a joint heap, storing pointers x and y , with accessible contents c_x, c_y , and version numbers v_x, v_y , respectively.² It requires several additional properties of the auxiliary histories. First, the combined history $\tau_s \cup \tau_o$ is continuous; that is, adjacent timestamps have matching states. Second, the last timestamp in $\tau_s \cup \tau_o$ correctly reflects what's stored in x and y . Finally, $W_{\mathcal{S}}$ also bakes in the properties (ii) – (iii) required in the proof outline of `readPair`.

The internal transitions wr_x and wr_y synchronize the changes to x and y with histories. In both transitions, $t_{\text{fresh}}^{\tau_s \cup \tau_o}$ is the smallest timestamp unused by τ_s and τ_o .

$$wr_x \triangleq \ell \xrightarrow{j} (x \mapsto (c_x, v_x) \cup y \mapsto (c_y, v_y)) \wedge \ell \xrightarrow{s} \tau_s \rightsquigarrow \\ \ell \xrightarrow{j} (x \mapsto (c'_x, v_x + 1) \cup y \mapsto (c_y, v_y)) \wedge \\ \ell \xrightarrow{s} \tau_s \cup t_{\text{fresh}}^{\tau_s \cup \tau_o} \mapsto \langle \langle c_x, c_y, v_x \rangle, \langle c'_x, c_y, v_x + 1 \rangle \rangle \\ wr_y \triangleq \ell \xrightarrow{j} (x \mapsto (c_x, v_x) \cup y \mapsto (c_y, v_y)) \wedge \ell \xrightarrow{s} \tau_s \rightsquigarrow \\ \ell \xrightarrow{j} (x \mapsto (c_x, v_x) \cup y \mapsto (c'_y, v_y + 1)) \wedge \\ \ell \xrightarrow{s} \tau_s \cup t_{\text{fresh}}^{\tau_s \cup \tau_o} \mapsto \langle \langle c_x, c_y, v_x \rangle, \langle c_x, c'_y, v_x \rangle \rangle \quad (17)$$

The first conjunct after \rightsquigarrow in wr_x (and wr_y is similar) allows that the version number of x can only increase by 1 in an atomic step. The second conjunct shows that simultaneously with the change of x , the snapshot of the changed state is committed to the self-history of the invoking thread. Together, wr_x and wr_y ensure that histories only grow, and only by adding valid snapshots; i.e., precisely the property (i) from Section 2.

\mathcal{U} also contains the identity transition `id`, whose presence enables programs that don't modify the state at all. In the pair-snapshot example, these are the `readX` and `readY` actions, and the `readPair` method. The pair-snapshot example doesn't involve ownership transfer, so \mathcal{S} has no external transitions, but these will be important in the forthcoming examples.

Entanglement and private heaps. Larger concurroids may be constructed out of smaller ones. A particularly common construction is *entanglement* [22]. Given concurroids \mathcal{U} and \mathcal{V} , the entanglement $\mathcal{U} \bowtie \mathcal{V}$ is a concurroid whose state space is the Cartesian product $W_{\mathcal{U}} \times W_{\mathcal{V}}$, and the transitions allow the \mathcal{U} portion to perform a \mathcal{U} transition, while the \mathcal{V} portion remains idle, and vice-versa. Additionally, \mathcal{U} and \mathcal{V} portions can communicate to *transfer a heap* between themselves, by having one take a heap-acquiring, and the other *simultaneously* taking a heap-releasing transition.

The most common is the entanglement with the concurroid \mathcal{P} of *private heaps* (see Appendix B.1). Entangling with \mathcal{P} lets the concurroids temporarily move heaps to a private section, via the communication discussed above, where threads may then perform the customary operations of reading, writing, allocating, and deal-

locating pointers, without interference.³ \mathcal{P} comes with a dedicated label `pv`. As an illustration, the following assertion may describe one possible state in the state space of the entanglement $\mathcal{P} \bowtie \mathcal{S}$ with the snapshot concurroid.

$$\text{pv} \xrightarrow{s} (z \mapsto 0) * \ell \xrightarrow{j} (x \mapsto (c_x, v_x) \cup y \mapsto (c_y, v_y))$$

The $\ell \xrightarrow{j} -$ portion describes the part of the state coming from \mathcal{S} , which is joint, containing pointers x and y , as explained before. The $\text{pv} \xrightarrow{s} (z \mapsto 0)$ describes the part of the state coming from \mathcal{P} . In this particular case, it contains a heap with a single pointer z . The heap is private, i.e., owned by the self thread, so z can't be modified by other threads. Notice that the assertions about `pv` and ℓ are separated by the resource separating conjunction $*$, which splits the state into portions with disjoint labels and heaps. In this particular case, it signifies that the labels `pv` and ℓ are distinct, as are the pointers z, x and y .

3.3 Extending and hiding concurroids

Concurroids represent concurrent data structures; thus it's important to be able to introduce and eliminate them. FCSL provides two programming constructors (both no-ops operationally), and corresponding inference rules for that purpose. For completeness, we introduce them here, but postpone the illustration until Section 4.

The injection rule shows that if a program is proved correct with respect to a smaller concurroid \mathcal{U} , then it can be extended to $\mathcal{U} \bowtie \mathcal{V}$, without invalidating the proof.

$$\frac{\{p\} c \{q\} @ \mathcal{U}}{\{p * r\} [c] \{q * r\} @ \mathcal{U} \bowtie \mathcal{V}} \quad r \subseteq W_{\mathcal{V}} \text{ stable under } \mathcal{V} \quad (18)$$

This is a form of framing rule, along the axis of adding new resources. The operator $*$ splits the state into portions with disjoint labels, and the side-condition that $r \subseteq W_{\mathcal{V}}$ forces r to remove the labels of the concurroid \mathcal{V} , so that c is verified wrt. the labels of \mathcal{U} . The program constructor $[-]$ is a coercion from \mathcal{U} to $\mathcal{U} \bowtie \mathcal{V}$.

Hiding is the ability to introduce a concurroid \mathcal{V} , i.e., install it in a private heap, for the scope of a thread c . The children forked by c can interfere on \mathcal{V} 's state, respecting \mathcal{V} 's transitions, but \mathcal{V} is hidden from the environment of c . To the environment, \mathcal{V} 's state changes look like changes of the private heap of c . Upon termination of c , \mathcal{V} is deinstalled.

$$\frac{\{ \text{pv} \xrightarrow{s} h * p \} c \{ \text{pv} \xrightarrow{s} h' * q \} @ (\mathcal{P} \bowtie \mathcal{U}) \bowtie \mathcal{V}}{\{ \Psi g h * (\Phi(g) \multimap p) \} \text{hide}_{\Phi, g} c \{ \exists g'. \Psi g' h' * (\Phi(g') \multimap q) \} @ \mathcal{P} \bowtie \mathcal{U}} \\ \text{where } \Psi g h = \exists k: \text{heap}. \text{pv} \xrightarrow{s} h \cup k \wedge \Phi(g) \text{ erases to } k \quad (19)$$

Since installing \mathcal{V} consumes a chunk of private heap, the rule requires the overall concurroid to support private heaps, i.e., to be an entanglement of \mathcal{P} with an arbitrary \mathcal{U} . In programs, we use the coercion `hide` c to indicate the change from $(\mathcal{P} \bowtie \mathcal{U}) \bowtie \mathcal{V}$ to $\mathcal{P} \bowtie \mathcal{U}$. If \mathcal{U} is of no interest, one can take it to be the empty concurroid \mathcal{E} , which is a right unit for \bowtie (see Appendix B.4).

The annotation Φ is a predicate; it describes an invariant that holds within the scope of `hide`, parametrized by an argument. It's subject to a number of conditions (see Appendix D.3). g is the initial argument, so $\Phi(g)$ holds in the initial state into which \mathcal{V} is placed upon installation. The rule guarantees that the ending state of c satisfies $\exists g'. \Phi(g')$. The surrounding connectives $*$ and \multimap merely mediate between \mathcal{U} , \mathcal{V} , and the erasure of \mathcal{V} to heaps. We explain the precondition, and the postcondition is similar.

In the precondition, $*$ separates private heaps from \mathcal{U} , and Ψ requires that every state in $\Phi(g)$ obtains the same private heap when the auxiliary fields are erased. \multimap is inherited from separation logic.

³ Our Coq proofs actually use two different concurroids, one for reading/writing, another for allocation/deallocation, which we entangle to provide all four operations. For simplicity, here we assume a monolithic implementation.

² Notice the overloading of the \mapsto notation for singleton heaps and histories.

```

1 push(e : A): Unit {
2   p <- alloc();
3   fix loop() {
4     p1 <- readSentinel();
5     write(p, (e, p1));
6     ok <- tryPush(p1, p);
7     if ok then return ();
8   else loop();}();
9 }
10 pop(): option A {
11   p <- readSentinel();
12   if p == null
13   then return None;
14   else {
15     (e,p1) <- readNode(p);
16     ok <- tryPop(p,p1);
17     if ok
18     then return Some e;
19   else return pop();}

```

Figure 3. Code of Treiber stack procedures.

$\Phi(g) \multimap p$ says that if the initial state (which is in W_u) is extended with a state from $\Phi(g)$ (which is in W_v), then the result is a state satisfying p . In other words, if a state satisfying $\Phi(g)$ is installed in the initial state of c , while its heap footprint is removed from the private heaps, then c 's precondition is satisfied.

4. Treiber stack and its client

In this section we illustrate how histories can be used to specify and verify the fine-grained data structure of Treiber stack [29]. We also show how the specs can be used by clients, where they provide an abstraction that facilitates client reasoning as if the structure were coarse-grained.

The Treiber stack works as follows. Physically, the stack is kept as a singly-linked list in the heap, with a sentinel pointer snt pointing to the stack top $p1$. $\text{push}(e)$ allocates a node p that's supposed to go to the top of stack, and attempts to link the node into the stack, by changing the sentinel to p . Clearly, this operation shouldn't succeed if some interfering thread has in the meantime changed the top by pushing or popping elements. Thus push applies a CAS read-modify-write operation [15], which atomically reads snt , compares its contents with $p1$, and if the two are equal (i.e., if the stack's top hasn't changed), writes p into snt , thus en-linking the new top. Otherwise, push is restarted.

$\text{pop}()$ behaves similarly. It reads the first node p , pointed to by snt , and obtains its value e and pointer $p1$ to the next node. Then it tries to de-link p , by changing the sentinel to $p1$ using a CAS to identify interference. Note that pop doesn't deallocate the de-linked node p , which thus remains in the data structure as garbage. This is by design, to prevent the ABA problem [15, §10]: if p is deallocated, then some other push may allocate it again, and place it back on top of the stack. A procedure that observed p on top of the stack, but hasn't performed its CAS yet may thus be fooled as follows. Its CAS may encounter p on top of the stack, and proceed as if the stack hadn't changed, producing invalid results.

The described code of the Treiber stack operations is given in Figure 3, where we used descriptive names for the atomic operations. Instead of CAS, we used tryPush and tryPop , and instead of pointer read, we used readSentinel and readNode . The reason for the descriptive names is that the atomic operations in FCSL operate not only on concrete heap pointers, but on auxiliary state as well. In the particular case of Treiber, the auxiliary state will be histories, which tryPush and tryPop change in different ways, even though they both operationally perform a CAS. Similarly, readSentinel and readNode deduce different facts about the histories, even though they both simply read from a pointer.

We elide here any further discussion on how the atomic operations are specified and verified in FCSL (it can be found in [22] and Appendix C). Instead, whenever needed, we simply state the Hoare specs for the atomics and proceed to use them in proof outlines, as if the atomics were ordinary procedures. Of course, our Coq files contain proofs that all such Hoare triples are valid.

Treiber concurroid. Given a label tb , the sentinel pointer snt , and the type A of the stack elements, the state space of the Treiber con-

curroid \mathcal{T} is described as follows. Its auxiliary self/other components are histories τ_s and τ_o that store mathematical sequences I corresponding to the logical contents of the stack at various timestamps. The joint component contains a heap h_s storing a sentinel snt pointing to a linked list, a heap h implementing the list, and a garbage section grb of de-linked nodes.

$$W_{\mathcal{T}} \triangleq \exists \tau_s \tau_o h_s. tb \xrightarrow{s} \tau_s \wedge tb \xrightarrow{o} \tau_o \wedge tb \xrightarrow{j} h_s \wedge I(\tau_s \cup \tau_o) h_s$$

$$I \tau h_s \triangleq \exists p h grb l. h_s = (snt \mapsto p) \cup h \cup grb \wedge list(p, l, h) \wedge \text{complete}(\tau) \wedge \text{continuous}(\tau) \wedge \text{stacklike}(\tau) \wedge \tau[\text{last}(\tau)] = l \quad (20)$$

The auxiliary predicates are:

$$list(p, l, h) \triangleq p = \text{null} \wedge l = \text{nil} \wedge h = \text{empty} \vee \exists e p' l' h'. l = e :: l' \wedge h = p \mapsto (e, p') \cup h' \wedge list(p', l', h')$$

$$\text{complete}(\tau) \triangleq \exists l_0. \tau(0) = (l_0, l_0) \wedge \forall t. t < |\text{dom}(\tau)| \Rightarrow t \in \text{dom}(\tau)$$

$$\text{stacklike}(\tau) \triangleq \forall t \in \text{dom}(\tau). t > 0 \Rightarrow \exists l. \tau(t) = (l, e :: l) \vee \tau(t) = (e :: l, e)$$

In particular: (1) the overall history $\tau_s \cup \tau_o$ is complete, i.e. no gaps exist between timestamps; (2) aside from the initialization in timestamp 0, the history only stores events corresponding to pushing or popping, and (3) the last recorded state in the history captures the current contents of the stack. For simplicity, we disable reasoning about the structure's inherent memory leak by not relating histories to grb in (20).

The transitions of \mathcal{T} allow for popping and pushing only.

$$\begin{aligned}
pop &\triangleq tb \xrightarrow{j} snt \mapsto p \cup h \cup grb \wedge tb \xrightarrow{s} \tau_s \wedge \\
&\quad h = (p \mapsto (e, p') \cup h') \wedge list(p, (e :: l), h) \rightsquigarrow \\
&\quad tb \xrightarrow{j} snt \mapsto p' \cup h' \cup (p \mapsto (e, p') \cup grb) \wedge \\
&\quad tb \xrightarrow{s} \tau_s \cup \tau_{\text{fresh}}^{\tau_s \cup \tau_o} \mapsto (e :: l, l) \\
push_{p',e,p} &\triangleq tb \xrightarrow{j} snt \mapsto p \cup h \cup grb \wedge tb \xrightarrow{s} \tau_s \wedge list(p, l, h) \rightsquigarrow \\
&\quad tb \xrightarrow{j} snt \mapsto p' \cup (p' \mapsto (e, p) \cup h) \cup grb \wedge \\
&\quad tb \xrightarrow{s} \tau_s \cup \tau_{\text{fresh}}^{\tau_s \cup \tau_o} \mapsto (l, e :: l)
\end{aligned}$$

In pop , the sentinel pointer is swapped from used-to-be head p to its next one, p' , whereas $(p \mapsto -)$ logically joins the garbage. The transition $push$ describes how a heap of the shape $p' \mapsto (e, p)$, describing the node to be pushed, is acquired and placed at the top of the stack. It's an external transition, which means it only fires when entangled with a concurroid from which the heap $p' \mapsto (e, p)$ can be taken away. In our case, that will be the concurroid \mathcal{P} for private state. Importantly, \mathcal{T} doesn't have a release transition; once a memory chunk is in the joint state, it never leaves, capturing that \mathcal{T} doesn't allow deallocation.

Method specs. We give the following history-based specs.

$$\begin{aligned}
\left\{ \begin{array}{l} pv \xrightarrow{s} \text{empty} * \\ tb \hookrightarrow (\text{empty}, -, \tau) \end{array} \right\} push(e) \left\{ \begin{array}{l} \exists l l'. pv \xrightarrow{s} \text{empty} * \\ tb \hookrightarrow (t \mapsto (l, e :: l), -, \tau) \wedge \tau < t \end{array} \right\} @ \mathcal{P} \times \mathcal{T} \\
\left\{ tb \hookrightarrow (\text{empty}, -, \tau) \right\} \\
pop() \\
\left\{ \begin{array}{l} \exists e t l. res = \text{Some } e \wedge tb \hookrightarrow (t \mapsto (e :: l, l), -, \tau) \wedge \tau < t \vee \\ \exists \tau_0 t. res = \text{None} \wedge tb \hookrightarrow (\text{empty}, \tau_0, \tau) \wedge \tau_0[t] = \text{nil} \end{array} \right\} @ \mathcal{T}
\end{aligned} \quad (21)$$

push runs with empty private heap and history, thus by framing, it can run with any private heap and history. After termination, the self history is incremented by a singleton exposing that a push event has been executed at a time stamp t ; $\tau < t$ indicates that the push event appeared strictly after the events preceding the call. The spec for pop is slightly more complicated as pop checks for stack emptiness, but ultimately proceeds in the similar manner. push works over the entangled concurroid $\mathcal{P} \times \mathcal{T}$, as it needs to allocate memory; pop works over \mathcal{T} only, as it doesn't deallocate.

In Figure 4 we present the proof outline for push .⁴ It's mostly self-explanatory, so we only point out a few technicalities. First,

⁴The proof for pop can be found in the Coq files.

```

1 {  $pv \xrightarrow{s} \text{empty} * tb \hookrightarrow (\text{empty}, -, \tau)$  }
2  $p \leftarrow [\text{alloc}()];$ 
3 {  $pv \xrightarrow{s} p \mapsto - * tb \hookrightarrow (\text{empty}, -, \tau)$  }
4 fix loop() {
5 {  $pv \xrightarrow{s} p \mapsto - * tb \hookrightarrow (\text{empty}, -, \tau)$  }
6  $p1 \leftarrow [\text{readSentinel}()];$ 
7 {  $pv \xrightarrow{s} p \mapsto - * tb \hookrightarrow (\text{empty}, -, \tau)$  }
8  $[\text{write}(p, (e, p1))];$ 
9 {  $pv \xrightarrow{s} p \mapsto (e, p1) * tb \hookrightarrow (\text{empty}, -, \tau)$  }
10  $\text{ok} \leftarrow \text{tryPush}(p1, p);$ 
11 {  $\text{ok} = \text{true} \wedge \exists t. l. pv \xrightarrow{s} \text{empty} * tb \hookrightarrow (t \mapsto (l, e :: l), -, \tau) \wedge \tau < t$  }
12 {  $\text{ok} = \text{false} \wedge pv \xrightarrow{s} p \mapsto (e, p1) * tb \hookrightarrow (\text{empty}, -, \tau)$  }
13 if ok then return ();
14 else
15 {  $pv \xrightarrow{s} p \mapsto - * tb \hookrightarrow (\text{empty}, -, \tau)$  }
16 loop(); }
17 {  $\exists t. l. pv \xrightarrow{s} \text{empty} * tb \hookrightarrow (t \mapsto (l, e :: l), -, \tau) \wedge \tau < t$  }

```

Figure 4. A proof outline of Treiber’s push method. The proof rule for **fix** allows assuming the spec of a procedure in the proof of the body, and is presented in Appendix D.

the atomic actions `alloc` and `write` are specific to the \mathcal{P} concurroid and have the following specs.

$$\begin{aligned} \{pv \xrightarrow{s} \text{empty}\} \text{ alloc}() \quad \{pv \xrightarrow{s} \text{res} \mapsto -\} @ \mathcal{P} \\ \{pv \xrightarrow{s} x \mapsto -\} \text{ write}(x, e) \quad \{pv \xrightarrow{s} x \mapsto e\} @ \mathcal{P} \end{aligned} \quad (22)$$

Thus, in Figure 4, they have to be explicitly injected into $\mathcal{P} \times \mathcal{T}$, by means of the coercion $[-]$ introduced in Section 3. Similarly for `readSentinel`, whose concurroid is \mathcal{T} . Somewhat surprisingly, the call to `readSentinel` in line 6 is irrelevant for the (partial) correctness of `tryPush`; thus line 7 doesn’t say anything about `p1`.⁵ The `tryPush` action appears in the proof outline with its precise specification; that is, line 9 contains its precondition, and 11 contains the postcondition, describing that a successful outcome of `tryPush` removed a heap from \mathcal{P} , moved it to the joint heap of \mathcal{T} , and updated the history to reflect the move, following the *push* transition.

Recovering sequential specifications. We next show that the subjective spec (21) is a generalization of the canonical sequential spec (1). In particular, if there’s no interference from other threads, (21) can be reduced to (1). The mechanism for achieving the reduction relies on the self/other dichotomy, thus substantiating our point that the dichotomy is important for precise reasoning with histories.

To this end, we use the `hide` constructor from Section 3. `Hide` introduces a concurroid in a delimited scope, and prohibits the environment threads from interfering on it. The heap for the introduced concurroid is appropriated from the private heap. In the case of *push*, we will appropriate a heap storing the sentinel and the linked list of the stack, install the \mathcal{T} concurroid over this heap, perform *push* with interference disabled, then return the heap back to private heaps. We will derive the following specification, which is essentially an elaborated version of (1), modulo the memory leak inherent to Treiber stack (hence *grb* in the postcondition).

$$\begin{aligned} \{ \exists p. h. pv \xrightarrow{s} (snt \mapsto p \cup h) \wedge \text{list}(p, l, h) \} \\ \text{hide}_{\Phi, \text{empty}} \{ \text{push}(e); \} \\ \{ \exists p. h. grb. pv \xrightarrow{s} (snt \mapsto p \cup h \cup grb) \wedge \text{list}(p, e :: l, h) \} @ \mathcal{P} \end{aligned} \quad (23)$$

The self/other dichotomy affords explicit access to other-owned histories, so that we can define the following predicate Φ stating

⁵Though, taking a random `p1` here will affect liveness, as *push* will keep looping until it finds the chosen `p1` at the top of the stack.

```

1 {  $\exists p. h. pv \xrightarrow{s} (snt \mapsto p \cup h) \wedge \text{list}(p, l, h)$  }
2 {  $\Psi \text{empty} * (\Phi(\text{empty}) \multimap tb \hookrightarrow (0 \mapsto (l, l), -, -))$  } by (25)
3  $\text{hide}_{\Phi, \text{empty}} \{$ 
4 {  $pv \xrightarrow{s} \text{empty} * tb \hookrightarrow (0 \mapsto (l, l), -, -)$  }
5  $\text{push}(e);$ 
6 {  $\exists t. l'. pv \xrightarrow{s} \text{empty} * tb \hookrightarrow (0 \mapsto (l, l) \cup t \mapsto (l', e :: l'), -, -)$  }
7 {  $\exists \tau. \Psi \tau \text{empty} * (\Phi(\tau) \multimap \exists t. l'. tb \hookrightarrow (0 \mapsto (l, l) \cup t \mapsto (l', e :: l'), -, -))$  }
8 {  $\exists t. l'. \tau. \tau = 0 \mapsto (l, l) \cup t \mapsto (l', e :: l') \wedge$  }
9 {  $\text{complete}(\tau) \wedge \text{continuous}(\tau) \wedge \Psi \tau \text{empty}$  }
10 {  $\exists \tau. \tau = 0 \mapsto (l, l) \cup 1 \mapsto (l, e :: l) \wedge \Psi \tau \text{empty}$  }
11 {  $\exists p'. h. pv \xrightarrow{s} (snt \mapsto p' \cup h \cup -) \wedge \text{list}(p', e :: l, h)$  } by (25)

```

Figure 5. Proof outline for sequential specification for *push*.

that other-histories remain empty within the scope of `hide`.

$$\Phi(\tau) \triangleq \exists l. tb \xrightarrow{s} ((0 \mapsto (l, l)) \cup \tau) \wedge tb \xrightarrow{o} \text{empty} \wedge W_{\mathcal{T}} \quad (24)$$

Inside `hide`, the stack is initialized (the history contains the singleton $0 \mapsto (l, l)$), there’s no interference ($tb \xrightarrow{o} \text{empty}$), and the state is a valid one for \mathcal{T} (i.e., it is captured by the definition (20)).

One can prove that if the histories are erased from any state in $\Phi(\tau)$, the remaining concrete heap consists of *snt* and the stack. Moreover, the contents of the stack is the last entry of τ (or l if τ is empty). In other words, using Ψ (19), defined in Section 3:

$$\Psi \tau \text{empty} \iff \exists p. h. pv \xrightarrow{s} (snt \mapsto p \cup h \cup -) \wedge \text{list}(p, l', h) \quad (25)$$

where $l' = \tau[\text{last}(\tau)]$ (or $l' = l$ if τ is empty).

The derivation is in Figure 5, and we comment on the main points. In line 2, the right conjunct uses the property inherent in Ψ , that $\Phi(\text{empty})$ erases to the heap storing l . Thus, this is the l that appears in the consequent of \multimap . In line 7, the right conjunct implies that the history τ , whose existence obtains from the rule for `hiding` (19), must be the self-history returned by *push*. Hence, it’s equal to $0 \mapsto (l, l) \cup t \mapsto (l', e :: l')$ for some t and l' . But, we also know that τ must be complete (no gaps between timestamps) and continuous. Hence $t = 1$ and $l' = l$ in line 9, which then derives the postcondition by (25).

A stack client. We next illustrate how the specs (21) are exploited by the *concurrent* clients of Treiber stack to abstract from the fine-grained nature of Treiber’s implementation. The example code in Figure 6 presents two procedures, *produce* and *consume*, that communicate via a common Treiber stack `tb`. *produce* pushes onto the stack the elements of its array `ap` in order, whereas *consume* pops from the stack, to fill its array `ac`. Both arrays are of equal size n . The procedure exchange runs *produce* and *consume* concurrently. Our goal is to prove that after exchange terminates, `ap` has been copied to `ac`, modulo element permutation. The inference will only use the specs (21) but not the code of Treiber methods, thus obtaining a coarse-grained view of effects inherent in the histories.

We use several auxiliary predicates. First, $\text{Arr}_n(a, l, h)$ defines an array of size n as a sequence of consecutive pointers in the heap h , starting from pointer a , and storing elements of the list l :

$$\text{Arr}_n(a, l, h) \triangleq |l| = n \wedge h = \bigcup_{i < n} (a + i) \mapsto l(i) \quad (26)$$

Next, the predicates *Pushed* and *Popped* extract the lists of pushed and popped elements from a stack history τ .

$$\begin{aligned} \text{Pushed}(\tau, l) &\triangleq l =_{\text{mset}} \{e \mid \exists t. l. t \mapsto (l, e :: l) \in \tau \vee 0 \mapsto (l, l) \in \tau \wedge e \in l\} \\ \text{Popped}(\tau, l) &\triangleq l =_{\text{mset}} \{e \mid \exists t. l. t \mapsto (e :: l, l) \in \tau\} \end{aligned} \quad (27)$$

The notation $\{--\}$ stands for multisets, and $=_{\text{mset}}$ is multiset equality, which we conflate with list equality modulo permutation. We can

```

1 produce(n: nat, i: nat) {
2   if i == n
3   then return ();
4   else {
5     e <- ap[i];
6     pushtb(e);
7     produce(i + 1);
8   }
9 }

1 consume(n: nat, i: nat) {
2   if i == n
3   then return ();
4   else {
5     r <- poptb();
6     if r == Some e
7     then {
8       ac[i] := e;
9       consume(i + 1);
10    } else consume(i);
11 }

```

```

1 exchange(n: nat): Unit { hideΦ, empty {
2   produce(n, 0); || consume(n, 0);
3 }}

```

Figure 6. A parallel stack-based producer/consumer program.

now ascribe the following specs to produce and consume:

$$\begin{aligned}
& \{ \text{Pr}(h_p, l_{<i}) \wedge \text{Arr}_n(\text{ap}, l, h_p) \} \text{produce}(n, i) \{ \text{Pr}(h_p, l) \wedge \text{Arr}_n(\text{ap}, l, h_p) \} \\
& \left\{ \begin{array}{l} \exists h_c \ l. \text{Cn}(h_c, l_{<i}) \wedge \\ \text{Arr}_n(\text{ac}, l, h_c) \end{array} \right\} \text{consume}(n, i) \left\{ \begin{array}{l} \exists h_c \ l. \text{Cn}(h_c, l) \wedge \\ \text{Arr}_n(\text{ac}, l, h_c) \end{array} \right\} \quad (28)
\end{aligned}$$

both over the $\mathcal{P} \times \mathcal{T}$ concurroid. Pr and Cn are defined as follows:

$$\begin{aligned}
\text{Pr}(h_p, l) &\triangleq \text{pv} \xrightarrow{s} h_p * \text{tb} \xrightarrow{s} \tau_s \wedge \text{Pushed}(\tau_s, l) \wedge \text{Popped}(\tau_s, \text{nil}) \\
\text{Cn}(h_c, l) &\triangleq \text{pv} \xrightarrow{s} h_c * \text{tb} \xrightarrow{s} \tau_s \wedge \text{Pushed}(\tau_s, \text{nil}) \wedge \text{Popped}(\tau_s, l),
\end{aligned}$$

so they essentially describe the producer/consumer loop invariants; $l_{<i}$ is a prefix of l for elements with indices less than i . The specs (28) show that produce pushes all the elements from ap, and consume fills ac with elements of some sequence of the length n . The proofs of both specs derive easily from (21) after these are framed to allow running in arbitrary initial self heap and history. We omit the proofs here, but provide them in the Coq files.

The interesting part of the example is proving exchange, where we compose produce and consume in parallel, and then use hiding to infer that the ap and ac arrays in the end contain the same elements, modulo permutation. The proof outline is in Figure 7, and it relies on the following important lemmas about histories.

Lemma 4.1 (Combining Pushed and Popped histories).

$$\text{Pushed}(\tau_1, l_1) \wedge \text{Popped}(\tau_1, \text{nil}) \wedge \text{Popped}(\tau_2, l_2) \wedge \text{Pushed}(\tau_2, \text{nil}) \implies \text{Pushed}(\tau_1 \cup \tau_2, l_1) \wedge \text{Popped}(\tau_1 \cup \tau_2, l_2)$$

Lemma 4.2. If τ is complete and stacklike, then

$$\text{Pushed}(\tau, l_1) \wedge \text{Popped}(\tau, l_2) \wedge |l_1| = |l_2| \implies l_1 =_{\text{mset}} l_2.$$

The proof outline in Figure 7 starts in the concurroid \mathcal{P} , which extends to $\mathcal{P} \times \mathcal{T}$ in the scope of hide. The invariant Φ of hide is the one we already used, defined in (24). It introduces a Treiber stack structure with an initial history $0 \mapsto (\text{nil}, \text{nil})$. Also, the heaplet $\text{snt} \mapsto \text{null}$ with the sentinel pointer has been donated to the state space of the Treiber stack, so it is removed from the private heap. Next, the self-heap and history are split via \otimes ; the parts are given to produce and consume, respectively, according to the parallel composition rule (10). Next, we reason out of specifications (28) for producer/consumer and combine the subjective views back via \otimes upon joining of the parallel threads: we thus derive that the contents of ap and ac, are l and l' respectively. By unfolding the definitions of Pr and Cn, and using Lemma 4.1, we derive $\text{Pushed}(\tau_s, l) \wedge \text{Popped}(\tau_s, l')$, where τ_s is the combined history of produce and consume. Finally, τ_s is complete and stack-like (since other-history is provably empty thanks to hiding). Moreover, both l and l' have size n , as ensured by the assertion Arr_n constraining both of them. Thus, in the last assertion, we can use Lemma 4.2 to obtain the desired equality of l and l' modulo permutation. Note also that the sentinel pointer is returned back to the private heap, along with the garbage heap (existentially abstracted by $-$).

$$\begin{aligned}
& \left\{ \text{pv} \xrightarrow{s} h_p \cup h_c \cup \text{snt} \mapsto \text{null} \wedge \text{Arr}_n(\text{ap}, l, h_p) \wedge \text{Arr}_n(\text{ac}, -, h_c) \right\} \\
& \quad \text{hide}_{\Phi, \text{empty}} \left\{ \begin{array}{l} \text{pv} \xrightarrow{s} h_p \cup h_c \wedge \text{Arr}_n(\text{ap}, l, h_p) \wedge \text{Arr}_n(\text{ac}, -, h_c) * \\ \text{tb} \xrightarrow{s} 0 \mapsto (\text{nil}, \text{nil}) \wedge \text{tb} \xrightarrow{o} \text{empty} \end{array} \right\} \\
& \left\{ \left(\text{pv} \xrightarrow{s} h_p \wedge \text{Arr}_n(\text{ap}, l, h_p) \right) \otimes \left(\text{pv} \xrightarrow{s} h_c \wedge \text{Arr}_n(\text{ac}, -, h_c) \right) \right\} \\
& \quad \left\{ * \text{tb} \xrightarrow{s} 0 \mapsto (\text{nil}, \text{nil}) \right\} \otimes \left\{ * \text{tb} \xrightarrow{s} \text{empty} \right\} \\
& \left\{ \text{Pr}(h_p, l_{<0}) \wedge \text{Arr}_n(\text{ap}, l, h_p) \right\} \parallel \left\{ \begin{array}{l} \text{produce}(n, 0); \\ \text{consume}(n, 0); \end{array} \right\} \\
& \quad \left\{ \text{Pr}(h_p, l) \wedge \text{Arr}_n(\text{ap}, l, h_p) \right\} \parallel \left\{ \begin{array}{l} \exists h_c \ l'. \text{Cn}(h_c, l') \wedge \text{Arr}_n(\text{ac}, l', h_c) \\ \exists h_c \ l'. \text{Cn}(h_c, l') \wedge \text{Arr}_n(\text{ac}, l', h_c) \end{array} \right\} \\
& \quad \left\{ \left(\text{Pr}(h_p, l) \wedge \text{Arr}_n(\text{ap}, l, h_p) \right) \otimes \left(\exists h_c \ l'. \text{Cn}(h_c, l') \wedge \text{Arr}_n(\text{ac}, l', h_c) \right) \right\} \\
& \left\{ \begin{array}{l} \exists h_c \ l'. \text{pv} \xrightarrow{s} h_p \cup h_c \wedge \text{Arr}_n(\text{ap}, l, h_p) \wedge \text{Arr}_n(\text{ac}, l', h_c) \\ * \exists \tau_s, \text{tb} \xrightarrow{s} \tau_s \wedge \text{Pushed}(\tau_s, l) \wedge \text{Popped}(\tau_s, l') \wedge \text{tb} \xrightarrow{o} \text{empty} \end{array} \right\} \\
& \quad \left\{ \begin{array}{l} \exists h_c \ l'. \text{pv} \xrightarrow{s} h_p \cup h_c \cup (\text{snt} \mapsto -) \cup - \wedge \\ \text{Arr}_n(\text{ap}, l, h_p) \wedge \text{Arr}_n(\text{ac}, l', h_c) \wedge l =_{\text{mset}} l' \end{array} \right\}
\end{aligned}$$

Figure 7. Proof outline for producer/consumer.

5. Flat combining

This section shows how PCMs in general, and histories in particular, can formalize the concurrent algorithm design pattern of helping, whereby one concurrent thread may execute code on behalf of another. We use Hendler *et al.*'s flat combining algorithm as an example [14]. Unlike other proofs of this algorithm [3, 30], we don't require any additional logical infrastructure aside from ordinary auxiliary state, represented by a PCM [19, 22]. We verify the algorithm *wrt.* a generic PCM, and then instantiate with the PCM of histories. Thus, our proof is usable even in examples where the specs don't rely on histories.

The flat combiner structure (FC) generalizes a coarse-grained lock [22, 23, 25] as follows. In the case of a lock, threads acquire exclusive access to the shared resource protected by the lock, *in succession*. With the flat combiner, threads register the work that they want to perform over the shared resource. The lock-acquiring thread (aka. the *combiner*) then executes all the registered work, so the other threads don't need to compete for the lock anymore. This reduces the contention on the lock, and improves performance. The higher-order flatCombine procedure (Figure 8) works as follows.⁶ It takes as input a *sequential* function f and argument x , and registers the invoking thread for help with executing $f \ x$ over the shared resource. It does so by storing $\text{Req } f \ x$ into the shared *publication* array, at index tid (line 2), where tid is the id of the invoking thread. It next enters the main loop (line 3) and tries to acquire the lock to the shared heap (line 4). The acquiring thread becomes a combiner (line 5); it traverses the publication array, checking for help requests (lines 6–11). For each request found (which can arrive even while the combiner holds the lock), the combiner executes the appropriate function with the provided arguments (line 9) over the shared heap. It informs the requesting thread i of the result w , by writing $\text{Resp } w$ into the slot i of the publication array (line 10). After the traversal, the combiner releases the lock (line 12). Finally, the thread (combiner or otherwise), checks the publication array to see if it has been helped (line 13). If so, it extracts the result w from its slot in the publication array, and fills the slot with Init (all line 13). The result of the help, if one exists, is returned in line 15. Otherwise, the thread loops for help again.

⁶For simplicity, we consider a modified version of the original algorithm. In particular, (a) we use an array rather than a priority queue for registration of help requests, and (b) we don't expunge help requests that haven't been served for sufficiently long time.

```

1 flatCombine(f: A → B, x: A): B {
2   reqHelp(tid, f, x);      // Request help for myself
3   fix loop() {             // Start looping for help
4     locked <- tryLock();    // Try to become a combiner
5     if locked then {       // Now I'm a combiner
6       for i ∈ {0, ..., n-1} { // Helping loop
7         req <- readReq(i);
8         if req == Req fi xi then {
9           w <- fi(xi);
10          doHelp(i, w);      // Notify i of helping
11        } }
12    unlock();               // Release the lock
13    rc <- tryCollect(tid);   // Try to collect my help
14    if rc == Some w         // I have been helped
15    then return w;          // Return the result
16  else return loop(); } }   // Try again

```

Figure 8. Code of the flat combining algorithm. n is a global variable bounding the number of threads.

To supply the intuition behind the proof, we first review how ordinary locks work with auxiliary state, in the subjective setting of FCSL [22]. As in CSL [23], and the Owicki-Gries method [25], a lock comes with a resource invariant I which relates the auxiliary state to the heap of the shared resource. When the lock is not taken, the shared heap satisfies I . When the lock is taken, the heap is in the exclusive possession of the acquiring thread, which can invalidate I , but has to restore it before releasing the lock. The subjective setting is similar, except the values of the auxiliary state are drawn from a PCM \mathbb{U} , and specs keep track of two values g_s and g_o , describing how much the thread (*self*) and its environment (*other*) have contributed to the resource, respectively. When the lock is free, the heap of the shared resource satisfies $I(g_s \bullet g_o)$. When the lock is released by a thread, the thread may update its g_s by some value g_Δ , reflecting that its contribution to the resource changed. Thus, if before locking, the resource satisfied $I(g_s \bullet g_o)$, after unlocking it will satisfy $I(g_s \bullet g_\Delta \bullet g_o)$.

The setup of the flat combiner is similar, but in addition to g_s and g_o , FC also keeps an array g_p storing a \mathbb{U} -value for each thread. The entry $g_p[i]$ signifies how much the thread i has been helped by the combiner. If $g_p[i] = g_\Delta$ is non-unit, i can collect the help by joining g_Δ to its own g_s , and setting $g_p[i]$ to the unit 1 of \mathbb{U} , after which it can ask for help again. Thus, the overall relation between the auxiliary state and the heap of the shared resource, when the lock is free, is captured by the invariant $I(\bigodot_{i=1}^n g_p[i] \bullet g_s \bullet g_o)$.

5.1 Flat combiner state and specs

The states of the FC concurrroid \mathcal{F} are described by the assertion:

$$W_{\mathcal{F}} \triangleq \text{fc} \mapsto (t_s, m_s, g_s) \wedge \text{fc} \mapsto (t_o, m_o, g_o) \wedge \text{fc} \mapsto (lk \mapsto b \cup h_p \cup h_r, g_p) \wedge \exists l_p. \text{Arr}_n(a_p, l_p, h_p)$$

The auxiliary state in the self/other components consists of the following. t_s and t_o are sets of thread ids, which form a PCM under disjoint union.⁷ m_s and m_o are elements of the *mutual exclusion* set $O = \{\text{Own}, \text{Own}\}$ [19, 22] and record whether the lock lk is owned by the thread, or the environment. O is a PCM under the operation defined as $x \bullet \text{Own} = \text{Own} \bullet x = x$, with $\text{Own} \bullet \text{Own}$ undefined. The unit element is Own , and the undefinedness of $\text{Own} \bullet \text{Own}$ means that two threads can't simultaneously own the lock. g_s and g_o are elements of a generic PCM \mathbb{U} , as described above. The self/other triples form a PCM with component-wise lifted joins and units.

The joint component of \mathcal{F} contains a concrete heap, and the auxiliary array g_p . The concrete heap keeps the pointer $lk \mapsto b$, which stands for the lock, with the boolean b representing the lock status. It also stores the publication array with the origin pointer a_p

into the heaplet h_p (see notation (26)). The array stores elements of type $\text{Stat} \triangleq \text{Init} \mid \text{Req } f \ x \mid \text{Resp } w$, as already apparent from Figure 8. We abuse the notation and refer to the array represented by h_p as a_p . The heap h_r is the resource protected by the FC lock. Upon locking it moves to the exclusive ownership of the combiner.

We further assume the following properties of $W_{\mathcal{F}}$:

- (i) for any tid , if $g_p[tid] \neq 1$, then $a_p[tid] = \text{Resp } w$ for some w ;
- (ii) if b is true then $h_r = \text{empty}$ and $m_s \bullet m_o = \text{Own}$; otherwise $m_s \bullet m_o = \text{Own}$ and $I(\bigodot_{i=1}^n g_p[i] \bullet g_s \bullet g_o) h_r$.

Property (i) ensures that the auxiliary array g_p holds a pending contribution in a cell tid only if the corresponding entry in the publication array a_p points to the response with some (uncollected) result. Property (ii) formally relates the auxiliary state to the resource heap h_r , as already described.

Now we can provide a spec for `flatCombine` in terms of the concurrroid \mathcal{F} . We assume $f : A \rightarrow B, x : A$, and f comes with the following spec over concurrroid \mathcal{P} for private heaps.⁸

$$\{\exists h. \text{pv} \mapsto h \wedge I \ g \ h\} f(x) \left\{ \exists h' \ g_\Delta. \text{pv} \mapsto h' \wedge I \ (g \bullet g_\Delta) \ h' \wedge f^\# x \text{ res } g \ g_\Delta \right\} \quad (29)$$

The spec allows the input heap h to change to h' . The resource invariant I has to be preserved, up to a change of the auxiliary state, from g to $g \bullet g_\Delta$. $f^\#$ is a client-supplied predicate which specifies f . We call it *validity predicate*; it's functional with respect to g_Δ , and relates the input value v , the result value res , the initial auxiliary state g and the “auxiliary delta” g_Δ resulting from the invocation of f . For instance, if f were a sequential push operation on stacks, with g and g_Δ being set to histories τ and τ_Δ , we might choose

$$\text{push}^\# x \text{ res } \tau \tau_\Delta \triangleq \text{res} = () \wedge \tau_\Delta = t_{\text{fresh}}^\tau \mapsto (l, x :: l), \quad (30)$$

where $l = \tau[\text{last}(\tau)]$. That is, $\text{push}^\#$ fixes the result of push to be unit and its effect to be the singleton history describing the action of pushing.

For the spec of `flatCombine` we need two auxiliary predicates. `NoReq` indicates that the thread tid currently requests no help. \hookrightarrow generalizes (6) from histories to PCM \mathbb{U} .

$$\text{NoReq}(tid) \triangleq \text{fc} \mapsto \{tid\}, \text{Own}, - \wedge a_p[tid] = \text{Init} \quad (31)$$

$$\text{fc} \hookrightarrow (g_s, g_o, g) \triangleq \text{fc} \mapsto (-, -, g_s) \wedge \text{fc} \mapsto (-, -, g_o) \wedge g \sqsubseteq \bigodot_{i=1}^n g_p[i] \bullet g_s \bullet g_o$$

Here, the partial order \sqsubseteq on PCM elements is defined as $g_1 \sqsubseteq g_2 \triangleq \exists g, g_2 = g_1 \bullet g$. It generalizes the relation \sqsubseteq from histories to the PCM \mathbb{U} , and in the specs captures that the value g_1 was “current” before g_2 .

The spec for `flatCombine` is given wrt. a specific thread tid .

$$\begin{aligned} & \{ \text{pv} \mapsto \text{empty} * \text{fc} \hookrightarrow (1, -, g) \wedge \text{NoReq}(tid) \} \\ & \text{flatCombine}(f, x) : B \\ & \left\{ \exists g' \ g_\Delta. \text{pv} \mapsto \text{empty} * \text{fc} \hookrightarrow (g_\Delta, -, g') \wedge \right. \\ & \quad \left. \text{NoReq}(tid) \wedge g \sqsubseteq g' \wedge f^\# x \text{ res } g' \ g_\Delta \right\} @ \mathcal{P} \rtimes \mathcal{F} \end{aligned} \quad (32)$$

`flatCombine` starts and ends in a state in which the thread tid doesn't request the help (`NoReq`), and in which g names the sum total of the contributions. It doesn't change the privately-owned heap, but increases self-contribution by amount of an auxiliary delta g_Δ . The mediating value g' is a sum-total of the contributions at the moment when the thread received help; thus, $f^\# x \text{ res } g' \ g_\Delta$. As g' is current sometime after the initial g , the spec postulates $g \sqsubseteq g'$.

5.2 Flat combiner transitions

External transitions intuitively correspond to locking/unlocking the heap h_r , thus moving it from the joint to private state, and vice-versa. We don't present them formally, as they are similar to the

⁷One thread may hold many thread id's, which it distributes between its children upon forking.

⁸Thus, we don't require f to be sequential, but every sequential function can be given a spec in \mathcal{P} .

```

1 {  $pv \xrightarrow{s} \text{empty} * fc \hookrightarrow (\mathbb{1}, -, g) \wedge \text{NoReq}(tid)$  }
2 [reqHelp(tid, f, x)];
3 {  $pv \xrightarrow{s} \text{empty} * fc \xrightarrow{s} (\{tid\}, \text{Own}, \mathbb{1}) \wedge \text{HasReq}(tid, f, x, g)$  }
4 fix loop() {
5 {  $pv \xrightarrow{s} \text{empty} * fc \xrightarrow{s} (\{tid\}, \text{Own}, \mathbb{1}) \wedge \text{HasReq}(tid, f, x, g)$  }
6 if tryLock() then {

Figure 9. Proof outline for flatCombine.

transitions in CSL [22]. The internal transitions *req*, *help* and *coll* synchronously change the contents of a_p and g_p for a particular thread i (one at a time) as the following diagram illustrates.

The transition *req* can be taken only by a thread holding the thread id i ; it changes the value of $a_p[i]$ from Init to Req $f \ x$ for some f and x . The transition *help* can be performed by any thread that owns the lock (not necessarily the one with the id i); it replaces the contents of $a_p[i]$ and $g_p[i]$ with an appropriate result w and an auxiliary delta g_{Δ} , respectively. The two are valid wrt. the input x and the cumulative auxiliary g_{all} , as ensured by the constraint $f^{\#}$. Finally, *coll* is invoked by the thread with id i ; it flushes the contents of $g_p[i]$, into the self-contribution g_s and puts Init into $a_p[i]$.

5.3 Verifying the flat combiner

Figure 9 presents the proof outline for flatCombine. We go over it in detail, providing specs for the employed atomic operations and auxiliary predicates as we go. The procedure starts by a call to reqHelp(tid, f, x) in line 2, which requests help for running f with argument x . The action reqHelp has the following spec:

$$\left\{ \begin{array}{l} fc \hookrightarrow (\mathbb{1}, -, g) \\ \wedge \text{NoReq}(tid) \end{array} \right\} \text{reqHelp}(tid, f, x) \left\{ \begin{array}{l} fc \xrightarrow{s} (\{tid\}, \text{Own}, \mathbb{1}) \\ \wedge \text{HasReq}(tid, f, x, g) \end{array} \right\} @ \mathcal{F} \quad (33)$$

where the auxiliary predicate HasReq is defined as follows:

$$\begin{aligned} \text{HasReq}(tid, f, x, g) &\triangleq \\ &\exists g_o. a_p[tid] = \text{Req } f \ x \wedge fc \xrightarrow{o} (-, -, g_o) \wedge g \sqsubseteq \bigodot_{i=1}^n g_p[i] \bullet g_o \vee \\ &\exists w \ g' \ g_o. a_p[tid] = \text{Resp } w \wedge g' \sqsubseteq \bigodot_{i=1}^n g_p[i] \bullet g_o \wedge \\ &\quad g_p[tid] = g_{\Delta} \wedge g \sqsubseteq g' \wedge f^{\#} \ x \ w \ g' \ g_{\Delta} \end{aligned}$$

HasReq indicates that once help is requested by a thread tid , it can remain unanswered. But if it's answered, then it's answered appropriately. That is, the result w and the auxiliary $g_p[tid]$ are obtained by a call to f , and are related by $f^{\#}$.

The assertion in line 3 serves as a loop invariant for lines 4–26. Right after entering the loop, the thread tries to acquire the shared resource by calling tryLock() in line 6. tryLock transfers the ownership of the heap h_r from \mathcal{F} to \mathcal{P} 's self-part (hence, its concurrroid is $\mathcal{P} \bowtie \mathcal{F}$) along with establishing the assertion Locked and invariant $I \ g_{all} \ h_r$. In the spec of tryLock below, g_{all} is a cumulative auxiliary value of \mathcal{F} . Notice that this value is stable under interference. The environment threads may collect their entries from g_p , and move them to their self components, but they can't change the sum total g_{all} .

$$\begin{aligned} &\left\{ \begin{array}{l} pv \xrightarrow{s} \text{empty} * fc \xrightarrow{s} (\{tid\}, \text{Own}, \mathbb{1}) \wedge \text{HasReq}(tid, f, x, g) \end{array} \right\} \\ &\quad \text{tryLock()} \\ &\left\{ \begin{array}{l} \text{res} = \text{true} \wedge \exists h_r \ g_{all}. pv \xrightarrow{s} h_r \wedge I \ g_{all} \ h_r * \text{LHR}(tid, f, x, g, g_{all}) \\ \vee \text{res} = \text{false} \wedge pv \xrightarrow{s} \text{empty} * fc \xrightarrow{s} (\{tid\}, \text{Own}, \mathbb{1}) \wedge \text{HasReq}(tid, f, x, g) \end{array} \right\} \end{aligned}$$

$$\text{LHR}(tid, f, x, g, g_{all}) \triangleq \text{Locked}(tid, g_{all}) \wedge \text{HasReq}(tid, f, x, g)$$

$$\text{Locked}(tid, g_{all}) \triangleq$$

$$\exists g_o. fc \xrightarrow{s} (\{tid\}, \text{Own}, \mathbb{1}) \wedge fc \xrightarrow{o} (-, -, g_o) \wedge g_{all} = \bigodot_{i=1}^n g_p[i] \bullet g_o$$

The assertion on line 7 serves as a loop invariant for the “combiner loop” of lines 8–18. The action readReq(i) in line 10 returns the contents of $a_p[i]$. The assertion in line 11 is stable since only the combiner can change the requests in a_p , by replacing them with responses. The call $f_i(x_i)$ in line 12 changes the assertion according to the spec (29), producing the result value w and an auxiliary delta g_{Δ} . Calling doHelp(i, w) changes the contents of $a_p[i]$ from Req $f_i \ x_i$ to Resp w and sets $g_p[i]$ to be g_{Δ} , following the transition *help*. This changes the cumulative value of \mathcal{F} 's auxiliaries from g_{all} to $g_{all} \bullet g_{\Delta}$, however, the invariant is preserved. Any assertion about i 's status isn't stable at this point (as nothing prevents $a_p[i]$ and $g_p[i]$ to be modified according to the transitions of \mathcal{F}), so we don't mention it on line 15. The combiner loop invariant on line 17 implies the precondition of the unlock action invoked on line 18, which releases the lock and transfers the ownership of h_r from \mathcal{P} 's self back to \mathcal{F} :

$$\left\{ \exists h_r \ g_{all}. pv \xrightarrow{s} h_r \wedge I \ g_{all} \ h_r * \text{LHR}(tid, f, x, g, g_{all}) \right\} \text{unlock()}$$

$$\left\{ pv \xrightarrow{s} \text{empty} * fc \xrightarrow{s} (\{tid\}, \text{Own}, \mathbb{1}) \wedge \text{HasReq}(tid, f, x, g) \right\} @ \mathcal{P} \bowtie \mathcal{F}$$

Regardless of whether the thread managed to be a combiner (lines 6–18) or not, it tries to collect its result and the contribution on line 20 by calling tryCollect action:

$$\begin{aligned} &\left\{ \begin{array}{l} fc \xrightarrow{s} (\{tid\}, \text{Own}, \mathbb{1}) \wedge \\ \text{HasReq}(tid, f, x, g) \end{array} \right\} \text{tryCollect}(tid) \left\{ \begin{array}{l} \text{Ack}(tid, f, x, g, \text{res}) \end{array} \right\} @ \mathcal{F} \\ &\text{Ack}(tid, f, x, g, r) \triangleq \\ &\quad r = \text{None} \wedge fc \xrightarrow{s} (\{tid\}, \text{Own}, \mathbb{1}) \wedge \text{HasReq}(tid, f, x, g) \vee \\ &\quad \exists w \ g' \ g_{\Delta}. r = \text{Some } w \wedge \text{NoReq}(tid) \wedge g \sqsubseteq g' \wedge \\ &\quad \quad fc \hookrightarrow (g_{\Delta}, -, g') \wedge f^{\#} \ x \ w \ g' \ g_{\Delta} \end{aligned} \quad (34)$$

Operationally, if the content of $a_p[tid]$ was Resp w , tryCollect replaces it by Init and simultaneously flushes the content g_{Δ} of $g_p[i]$ into the self-component, returning Some w as its result; otherwise it returns None without changing anything. The predicate Ack describes these two possible outcomes. The rest of the proof goes by

branching on the result of `tryCollect` (line 22), selecting the appropriate disjunct from `Ack` (34), and restarting the loop if `None` was returned (line 26).

5.4 Instantiating the flat combiner for stacks

To illustrate that the abstract spec for the flat combiner follows the expected intuition, we consider an instance where g_s, g_o, g_p are histories, and f is the sequential push method for stacks, satisfying the generic sequential spec (29) with the validity predicate $\text{push}^\#$ defined by (30) and the stack invariant (20). So by instantiating (32), after some simplification, we obtain:

$$\begin{aligned} & \{ \text{pv} \xrightarrow{s} \text{empty} * \text{fc} \hookrightarrow (\text{empty}, -, \tau) \wedge \text{NoReq}(tid) \} \\ & \text{flatCombine}(\text{push}, e) : \text{Unit} \\ & \{ \exists t. \text{pv} \xrightarrow{s} \text{empty} * \text{fc} \hookrightarrow (t \mapsto (l, e :: l), -, \tau) \wedge \tau < t \wedge \text{NoReq}(tid) \} \end{aligned} \quad (35)$$

Note that (35) is very similar to the spec (21) for Treiber push; the only difference is in the FC-specific components such as thread id's, the `NoReq` predicate, and the lock status views used in the definition of `NoReq`. Thus, the spec (32) is adequate.

Strictly speaking, instantiating (32) yields the postcondition:

$$\{ \exists \tau' \tau_\Delta. \text{pv} \xrightarrow{s} \text{empty} * \text{fc} \hookrightarrow (\tau_\Delta, -, \tau') \wedge \tau \sqsubseteq \tau' \wedge \text{push}^\# e () \tau' \tau_\Delta \wedge \dots \}$$

but this can be easily weakened into (35). The main difficulty is in deriving the assertion $\tau < t$ in (35)'s postcondition. Intuitively, the assertion holds because t , such that $\tau_\Delta = t \mapsto (l, e :: l)$, has been taken to be *fresh wrt.* τ' by definition of $\text{push}^\#$ (30). Thus, $\tau' < t$, so the result follows from $\tau \sqsubseteq \tau'$. A similar derivation can be done for an FC-specification of `pop`.

6. Related and future work

Histories are a recurring idea in the semantics of shared-memory concurrency, in one form or another. For example, the classical Brookes' semantics [1] uses *traces* to give a model for CSL. Traces are similar to histories, but don't contain time stamps. The explicit time-stamping makes it straightforward to define a merge (*i.e.*, join) for histories, and endows them with PCM structure. While Brookes uses traces in the semantics, we use histories in the specs.

Temporal reasoning about shared-memory concurrent programs has also been employed before. For example, O'Hearn *et al.* [24] advocate *hindsight lemmas* to directly and elegantly capture the intuition about linearizability of a class of concurrent data structures and algorithms. In this paper, we put histories to use in ordinary Hoare-style specs. This avoids the relational reasoning about permuting traces of *two* programs, as required by linearizability, but is strong enough to provide Hoare logic specs that are expressive, and capable of abstracting granularity. In our Coq formalization, we discovered that deriving stability of history-based specs very much resembles reasoning by hindsight.

HLRG by Fu *et al.* is a Hoare logic for concurrency which admits history-based assertions [10]. However, their histories are hard-coded into the logic. In contrast, our histories are just a specific PCM, that one can use to instantiate the general framework of FCSL. This affords greater flexibility: if history-based specifications are not needed (*e.g.*, the incrementation example [22]), they don't have to be used. HLRG defines separating conjunction $*$ over histories as follows: conjoined histories must have equal length, and their corresponding entry heaps are merged via disjoint union. In contrast, our histories are not required to have heaps in the codomain. One can choose an arbitrary datatype to capture what is important for an example at hand.

Gotsman *et al.* use temporal reasoning to verify several concurrent memory reclamation algorithms using the notion of *grace period* [12]. Their logic extends RGSep [33] with a very specific notion of histories, which live in the shared state. In contrast, we use histories not as shared, but as private auxiliary state, follow-

ing the self/other dichotomy. This enables us to directly reuse the frame rule and other logical infrastructure from the separation logic FCSL, without any extensions.

Several recent approaches, such as Turon *et al.*'s CaReSL [30] (which also verifies the flat combiner), and the logic of Liang and Feng (L&F) [20] support granularity abstraction by unifying Hoare-style reasoning with linearizability and contextual refinement. In contrast, in this paper, we argue that a form of granularity abstraction can already be obtained without relying on linearizability. Instead, by using histories, one obtains Hoare-style specs which hide the fine-grained nature of the underlying programs. This can be done in a simple Hoare logic (and we reuse FCSL off the shelf), whereas CaReSL and L&F require significant additional logical infrastructure [20, 21, 31], as linearizability is a stronger property than our specs. One example of the additional infrastructure has to do with helping (*e.g.*, in the flat combiner), where these logics consider the refined effectful commands as resources, and make them subject to ownership transfer [30]. While on the surface there's a similarity between commands-as-resources and histories-as-resources, there are also significant differences. Commands-as-resources are about executing specification-level programs (and an effectful abstract program, once executed, can't be "re-executed", since it has reached a value), while histories are about what has transpired. Unlike commands-as-resources, histories also contain information about the order in which something happened in the form of timestamps, thus enabling temporal reasoning by hindsight [24]. Histories have a PCM structure, whereas commands-as-resources don't. Hence, histories in FCSL are subject to the same set of inference rules as heaps, in contrast to commands-as-resources which requires a number of dedicated inference rules.

Many of our history-based proofs are very close in spirit to proofs of linearizability (*e.g.*, the proofs of Treiber stack in Section 4 compared to the proofs in L&F [20]), since adding an entry to a self-history can be seen as linearizing an effectful operation. However, we obtain some simplification in the proofs of pure methods such as `readPair`. In particular, L&F and related logics require *prophecy variables* [26] (or, equivalently, *speculations* [20, 31]) in their proofs of `readPair`, but we don't. We do expect, however, that prophecy variables will be required in examples where the shape of the event to be inserted into the history can't be fully determined at the moment when it logically takes place (*e.g.*, Harris *et al.*'s MCAS [13, 32]). We plan to address such examples in the future work, by choosing another history-based PCM; that of branching-time histories, in contrast to the linear-time ones used here.

In this work, we argued for the abstraction of atomicity via the singleton histories of the form $t \mapsto (s_1, s_2)$, which describe the atomic changes in the abstract state. A different approach to express atomicity abstraction is suggested by da Rocha Pinto *et al.*'s logic TaDA [4] (a successor of the Concurrent Abstract Predicates framework (CAP) [5]) using the notion of an "atomic Hoare triple" of the form $\langle p \rangle c \langle q \rangle$, where the precondition p is required to be stable, whereas q is not. Such triples can be explicitly stabilized to obtain specs similar to (2). TaDA proposes a *make_atomic* command and a number of related inference rules, which allow one to specify synchronized changes of auxiliary resources across several shared regions. The changes themselves don't have to be physically atomic; it's sufficient that they appear atomic from the point of view of specs. TaDA's assertions range over *atomic tracking* resources, similar to the operations-as-resources in the linearizability proofs [20, 30]. Unlike histories, these resources don't have the PCM structure, and thus require special treatment in TaDA's metatheory. The atomic tracking resources aren't subject of ownership transfer, which is why TaDA currently doesn't support reasoning about helping.

Yet another view of atomicity abstraction and canonical concurrent specifications, which also bypasses linearizability, is advocated by Svendsen *et al.* in a series of papers on Higher-Order and Impredicative Concurrent Abstract Predicates [27, 28]. Both HOCAP and iCAP leverage the idea, originated by Jacobs and Piessens [17], of parametrizing specs of concurrent data types by a user-provided auxiliary code. Such auxiliary code can be seen as a callback, which, when invoked at some point during the execution of a specified method, changes the values of auxiliary resources in several regions simultaneously. Thus, when proving a parametrized spec, one should locate a right moment to invoke the provided auxiliary code, so its precondition would be ensured and the postcondition handled properly, a reasoning similar to locating a linearization point. The use of the first-class auxiliary code can introduce circularity in the domain underlying the logic—the issue tackled in HOCAP by means of indirection via “region types” and resolved in iCAP by providing a (non-elementary) model in the topos of trees, which enables reasoning about helping.

One difference between iCAP and TaDA is that *make_atomic* in TaDA presents a more localized view of atomicity, whereas the specs in iCAP have to predict the uses of the data structure, and provide hooks for callbacks. The hooks lead to somewhat indirect specs, and pollute the reasoning about the structure with client-side information. We haven’t considered either of these two ways of exploiting abstract atomicity in the current paper, but plan to add *make_atomic* to FCSL in the future work. The challenge will be to generalize *make_atomic* to work with different notions of histories (e.g., branching-time histories may be useful, as mentioned above). We believe that the PCM approach (together with subjectivity), neither of which is exploited by TaDA and iCAP, will be beneficial in that respect. In particular, we plan to use PCMs to generalize the notion of logical atomicity afforded by histories, that we explored in this paper. Given a PCM \mathbb{U} , the element $x \in \mathbb{U}$ is *prime* if it can’t be represented as $x = x_1 \bullet x_2$, for non-unit x_1, x_2 . For example, in the PCM of heaps, the prime elements are the singleton heaps. In the PCM of natural numbers with multiplication, the prime elements are the prime numbers. In the PCM of histories, the prime elements are the singleton histories $t \mapsto a$. A program can be considered logically atomic if it augments the self-owned portion of its state by a prime element, or by a unit. According to this definition, all the examples presented in this paper are atomic. We expect it should be possible to soundly apply *make_atomic* to programs that are atomic in this logical sense.

7. Conclusion

In this work we proposed using specifications over auxiliary state in the form of histories as means of providing general specs for fine-grained concurrent data structures in a separation style logic.

We relied on singleton time-stamped histories $t \mapsto a$, to specify that a program at time t performs an action a . The action is viewed as *logically* atomic, even though the program may implement it in a fine-grained manner. Client programs that reason with this spec can treat the program as if it were coarse-grained. Thus, in the context of Hoare logic, history-based specs can achieve one of the main goals behind linearizability.

Histories satisfy the algebraic properties of PCMs, and thus can directly reuse the underlying infrastructure from an employed separation logic, such as the assertion logic and the frame rule. Furthermore, as we illustrated with the proof of the flat combiner algorithm in Section 5, the concept of ownership transfer from separation logic, when specialized to the PCM of histories, directly formalizes the design pattern of helping.

In addition to the flat combiner, we have verified a number of benchmark fine-grained structures, such as the pair snapshot structure, and the Treiber stack. The interesting and novel point

about the specs and the proofs is that they all rely in an essential way on the subjective dichotomy between self and other auxiliary state, in order to directly relate the result of a program execution with the interference of other threads. Such explicit dichotomy provides for what we consider very concise proofs. We substantiate this observation by mechanizing all the reasoning in Coq.

Optional appendices

In the optional appendices we provide detailed overview of main concepts of Fine-grained Concurrent Separation Logic (FCSL), necessary for the formal reasoning. These include semantics of the logical assertions as well as inference rules. We address the curious reader to the original paper on FCSL [22] and its extended version (or the Coq development accompanying this manuscript) for the details of FCSL's denotational semantics and the soundness proof. **Appendix A** provides the formal semantics of the FCSL assertions. **Appendix B** formally presents concurroids and entanglement, along with several examples. **Appendix C** describes properties of atomic actions of FCSL concurroids. Finally, **Appendix D** provides the rules of FCSL, explaining some of them in detail.

A. Semantics of FCSL assertions

State in FCSL is divided along two different axes. The first axis is labels (isomorphic to nat). Labels identify concurroids, *i.e.* data structures that are stored in the state, with specific restrictions on their evolution. The second axis is ownership. Each label contains self, other and joint component, describing how much of each concurroid is owned privately by the specified thread, privately by that thread's environment, and how much is shared, respectively.

To formally define the concept, we introduce the notion of PCM-map and type-maps. A PCM-map is a finite map from labels to a dependent product $\Sigma_{\mathbb{U}; \text{pcm}} \mathbb{U}$, where \mathbb{U} is a PCM, and $v \in \mathbb{U}$. A type map is similar, except we don't require the range to be a PCM; it can be an arbitrary type.

PCM-maps are composed by means of two operations. Disjoint union $m_1 \cup m_2$ collects the labels from m_1 and m_2 , ensuring that there's no overlap. This operation applies to type-maps as well. However, PCM-maps have another operation which doesn't apply to type-maps: $m_1 \circ m_2$ joins the values of individual labels, *i.e.*, $\text{empty} \circ \text{empty} = \text{empty}$, and $((\ell \mapsto_{\mathbb{U}} v_1) \cup m'_1) \circ ((\ell \mapsto_{\mathbb{U}} v_2) \cup m'_2) = (\ell \mapsto_{\mathbb{U}} v_1 \bullet v_2) \cup (m'_1 \circ m'_2)$, and undefined otherwise.

State, ranged over by w , is a triple $[s \mid j \mid o]$, where s and o are PCM-maps, and j is a type map. We refer to them as *self*, *other*, and *joint* components of w . In specifications, the three components signify different state ownership: s is the state owned by the specified thread, and is inaccessible to the environment; o is the state owned by the environment, and is inaccessible to the specified thread; j is the shared (or joint) state, accessible to every thread. Notice that unlike s and o which are PCM-maps, j is a type-map. In other words, the joint component is not subject to PCM-laws, as we don't shuffle its components upon forking, joining, and framing, as we do in the cases of s and o .

The state $w = [s \mid j \mid o]$ is valid iff:

$w \models \top$	iff always
$w \models \ell \mapsto^s v$	iff valid w , and $w = w_1 \cup w_2$, and $w_1.s = \ell \mapsto v$
$w \models \ell \mapsto^j h$	iff valid w , and $w = w_1 \cup w_2$, and $w_1.j = \ell \mapsto v$
$w \models \ell \mapsto^o v$	iff valid w , and $w = w_1 \cup w_2$, and $w_1.o = \ell \mapsto v$
$w \models p \wedge q$	iff $w \models p$ and $w \models q$
$w \models p * q$	iff valid w , and $w = w_1 \cup w_2$, and $w_1 \models p$ and $w_2 \models q$
$w \models p \multimap q$	iff for every w_1 , valid $w \cup w_1$, $w_1 \models p$ implies $w \cup w_1 \models q$
$w \models p \otimes q$	iff valid w , and $w.s = s_1 \cup s_2$, and $[s_1 \mid w.j \mid s_2 \circ w.o] \models p$ and $[s_2 \mid w.j \mid s_1 \circ w.o] \models q$
$w \models \text{this } w'$	if $w = w'$
$\models p \downarrow h$	iff for every valid w , $w \models p$ implies $[w] = h$
valid w	iff $w = [s \mid j \mid o]$, $\text{dom } s = \text{dom } j = \text{dom } o$, $s \circ o$ is defined, and the heaps in s, j, o are disjoint
$[w]$	$\hat{=}$ disjoint union of all the heaps in w
$w_1 \cup w_2$	$\hat{=}$ pairwise disjoint union of $w_{1,2}$'s PCM-components
$\ell \mapsto [v_s \mid v_j \mid v_o]$	$\hat{=}$ $[\ell \mapsto v_s \mid \ell \mapsto v_j \mid \ell \mapsto v_o]$

Figure 10. Notation and semantics of main FCSL assertions.

- (i) the components s , j and o contain the same labels.
- (ii) $s \circ o$ is defined, *i.e.*, equals labels in s and o contain equal PCMs. Notice that the labels in j are independent, and may contain elements of other types;
- (iii) the heaps that may be stored in the labels of s , j , o are disjoint.

Figure 10 collects the definitions the main assertions of FCSL in terms of the two operations on PCM-maps.

B. Concurroids: properties and examples

A concurroid is a 4-tuple $\mathcal{U} = (L, W, I, E)$ where: (1) L is a set of labels, where a label is a nat; (2) W is the *set of states*, each state $w \in W$ having the structure described in Section A; (3) I is the set of *internal transition*, which are relations on W and one of which is always an identity relation id ; (4) E is a set of pairs (α, ρ) , where α and ρ are *external transitions* of \mathcal{U} . An external transition is a function, mapping a heap h into a relation on W . The components must satisfy a further set of requirements, discussed next.

State properties. Every state $w \in W$ is valid as defined in Figure 10, and its label footprint is L , *i.e.* $\text{dom } (w.s) = \text{dom } (w.j) = \text{dom } (w.o) = L$. Additionally, W satisfies the property:

$$\text{Fork-join closure: } \forall t: \text{PCM-map. } w \triangleleft t \in W \iff w \triangleright t \in W, \\ \text{where } w \triangleleft t = [t \circ w.s \mid w.j \mid w.o], \\ \text{and } w \triangleright t = [w.s \mid w.j \mid t \circ w.o]$$

The property requires that W is closed under the realignment of *self* and *other* components, when they exchange a PCM-map t between them. Such realignment is part of the definition of \otimes , and thus appears in proofs whenever the rule PAR (10) is used, *i.e.* whenever threads fork or join. Fork-join closure ensures that if a parent thread forks in a state from W , then the child threads are supplied with states which also are in W , and dually for joining.

Transition properties. A concurroid transition γ is a relation on W satisfying:

$$\text{Guarantee: } (w, w') \in \gamma \implies w.o = w'.o \\ \text{Locality: } \forall t: \text{PCM-map. } w.o = w'.o \implies \\ (w \triangleright t, w' \triangleright t) \in \gamma \implies (w \triangleleft t, w' \triangleleft t) \in \gamma$$

Guarantee restricts γ to only modify the *self* and *joint* components. Therefore, γ describes the behavior of a viewing thread in the subjective setting, but not of the thread's environment. In the terminology of Rely-Guarantee logics [7, 8, 33], γ is a *guarantee* relation. To describe the behavior of the thread's environment, *i.e.*, obtain a *rely* relation, we merely *transpose* the self and other components of γ .

$$\gamma^\top = \{(w_1^\top, w_2^\top) \mid (w_1, w_2) \in \gamma\}, \text{ where } w^\top = [w.o \mid w.j \mid w.s] \quad (36)$$

In this sense, FCSL transitions always encode *both* guarantee and rely relations.

Locality ensures that if γ relates states with a certain *self* components, then γ also relates states in which the *self* components have been simultaneously *framed* by a PCM-map t , *i.e.*, enlarged according to t . It thus generalizes the notion of locality from separation logic, with a notable difference. In separation logic, the frame t materializes out of nowhere, whereas in FCSL, t has to be appropriated from *other*; that is, taken out from the ownership of the environment.

An *internal* transition ι is a transition which preserves heap footprints. An *acquire* transition α , and a *release* transition ρ are functions mapping heaps to transitions which extend and reduce heap footprints, respectively, as show below. An external transition is either an acquire or a release transition. If $(\alpha, \rho) \in E$, then α is an acquire transition, and ρ is a release transition.

$$\begin{aligned} \text{Footprint preservation} & : (w, w') \in \iota \implies \text{dom } [w] = \text{dom } [w'] \\ \text{Footprint extension} & : \forall h:\text{heap}. (w, w') \in \alpha(h) \implies \\ & \quad \text{dom } ([w] \cup h) = \text{dom } [w'] \\ \text{Footprint reduction} & : \forall h:\text{heap}. (w, w') \in \rho(h) \implies \\ & \quad \text{dom } ([w'] \cup h) = \text{dom } [w] \end{aligned}$$

The set of Internal transitions always includes at least the identity transition *id* (*i.e.*, transition from a state to itself). Footprint preservation requires internal transitions to preserve the domains of heaps obtained by state flattening. Internal transitions may exchange the ownership of subheaps between the *self* and *joint* components, or change the contents of individual heap pointers, or change the values of non-heap (*i.e.*, auxiliary) state, which flattening erases. However, they cannot add new pointers to a state or remove old ones, which is the task of external transitions, as formalized by Footprint extension and reduction.

B.1 The concurrend of private heaps

The private heap concurrend is defined as follows.

$$\mathcal{P} = (\{pv\}, W_{\mathcal{P}}, \{\iota_{\mathcal{P}}, \text{id}\}, \{(\alpha_{\mathcal{P}}, \rho_{\mathcal{P}})\}) \quad (37)$$

It is identified by a *fixed* dedicated label *pv* and directly captures the notion of heap *ownership*, as presented in CSL [23]. Its state-space $W_{\mathcal{P}}$ is defined as a set of states of the shape

$$pv \mapsto [h_s \mid \text{empty} \mid h_o],$$

where h_s and h_o are disjoint heaps (which are known to form a PCM). The concurrend's *internal* transitions $\iota_{\mathcal{P}}$ allow the values in the codomain of the heap h_s , privately-owned by *self*, to be changed arbitrarily. There is only one channel of acquire/release transitions $\alpha_{\mathcal{P}}$ and $\rho_{\mathcal{P}}$ that account for the addition/removal of a heap chunk to/from h_s correspondingly, given that the state validity is preserved. Transitions of \mathcal{P} can be formally defined using the notation from Figure 10 as follows:

$$\begin{aligned} \iota_{\mathcal{P}} & \equiv pv \xrightarrow{s} (x \mapsto v \cup h_s) \rightsquigarrow pv \xrightarrow{s} (x \mapsto w \cup h_s) \\ \alpha_{\mathcal{P}}(h) & \equiv pv \xrightarrow{s} h_s \rightsquigarrow pv \xrightarrow{s} (h_s \cup h) \\ \rho_{\mathcal{P}}(h) & \equiv pv \xrightarrow{s} (h_s \cup h) \rightsquigarrow pv \xrightarrow{s} h_s \end{aligned} \quad (38)$$

Importantly, as demonstrated by the rule *fo hiding* (19), the concurrend \mathcal{P} serves as the primary one in FCSL: all other concurrends are it in a scoped manner via the *hiding* mechanism (see Appendix D). In order to describe allocation/deallocation, the private heap concurrend is typically being entangled with an allocator concurrend \mathcal{A} , which we have implemented in Coq as an instance of a spin-lock with a specific resource invariant (see Section B.2), but omitted from the presentation. The entangled concurrend $\mathcal{P} \bowtie \mathcal{A}$ is referred to as simply \mathcal{P} in the main body of the paper.

B.2 The concurrend for a spin-lock

A simple CAS-based spin-lock is defined by the concurrend

$$\mathcal{L}_{lk, lk, Inv} = (\{lk\}, W_{\mathcal{L}}, \{\text{id}\}, \{(\alpha_{\mathcal{L}}, \rho_{\mathcal{L}})\})$$

with $W_{\mathcal{L}} = \{w \mid w \models \text{assertion (39)}\}$, where

$$\begin{aligned} lk \xrightarrow{s} (m_s, g_s) \wedge lk \xrightarrow{o} (m_o, g_o) \wedge lk \xrightarrow{j} ((lk \mapsto b) \cup h) \wedge \\ \text{if } b \text{ then } h = \text{empty} \wedge m_s \bullet m_o = \text{Own} \\ \text{else } Inv(g_s \bullet g_o) h \wedge m_s \bullet m_o = \text{Own} \end{aligned} \quad (39)$$

The assertion states that if the lock is taken ($b = \text{true}$) then the heap h is given away, otherwise it satisfies the resource invariant *Inv*. In either case, the thread-relative views m_s , m_o , g_s and g_o are consistent with the resource's views of lk and h . Indeed, notice how m_s , m_o and g_s , g_o are first \bullet -joined (by the \bullet -operations of $O = \{\text{Own}, \text{Own}\}$, defined in Section 5, and a client-provided PCM \mathbb{U} , respectively) and then related to b and h ; the former implicitly by the conditional, the latter explicitly, by the resource invariant *Inv*, which is now parametrized by $g_s \bullet g_o$.

The external transitions of the lock are defined as follows (assuming $w.o = w'.o$ everywhere):

$$\begin{aligned} (w, w') \in \alpha_{\mathcal{L}}(h) & \iff \begin{aligned} w.s & = lk \mapsto (\text{Own}, g_s), \\ w.j & = lk \mapsto (lk \mapsto \text{true}), \\ w'.s & = lk \mapsto (\text{Own}, g'_s), \\ w'.j & = lk \mapsto ((lk \mapsto \text{false}) \cup h) \end{aligned} \\ (w, w') \in \rho_{\mathcal{L}}(h) & \iff \begin{aligned} w.s & = lk \mapsto (\text{Own}, g_s), \\ w.j & = lk \mapsto ((lk \mapsto \text{false}) \cup h), \\ w'.s & = lk \mapsto (\text{Own}, g_s), \\ w'.j & = lk \mapsto (lk \mapsto \text{true}) \end{aligned} \end{aligned}$$

The internal transition admits no changes to the state w . The $\alpha_{\mathcal{L}}$ transition corresponds to unlocking, and hence to the acquisition of the heap h . It flips the ownership bit from *Own* to *Own*, the contents of the lk pointer from *true* to *false*, and adds the heap h to the resource state. The $\rho_{\mathcal{L}}$ transition corresponds to locking, and is dual to $\alpha_{\mathcal{L}}$. When locking, the $\rho_{\mathcal{L}}$ transition keeps the auxiliary view g_s unchanged. Thus, the resource “remembers” the auxiliary view at the point of the last lock. Upon unlocking, the $\alpha_{\mathcal{L}}$ transition changes this view into g'_s , where g'_s is some value that is coherent with the acquired heap h , *i.e.*, which makes the resource invariant *Inv* ($g_s \bullet g_o$) h hold, and thus, the whole state belongs to $W_{\mathcal{L}}$.

B.3 Entanglement

Let $\mathcal{U} = (L_{\mathcal{U}}, W_{\mathcal{U}}, I_{\mathcal{U}}, E_{\mathcal{U}})$ and $\mathcal{V} = (L_{\mathcal{V}}, W_{\mathcal{V}}, I_{\mathcal{V}}, E_{\mathcal{V}})$, be concurrends. The entanglement $\mathcal{U} \bowtie \mathcal{V}$ is a concurrend with the label component $L_{\mathcal{U} \bowtie \mathcal{V}} = L_{\mathcal{U}} \cup L_{\mathcal{V}}$. The state set component combines the individual states of \mathcal{U} and \mathcal{V} by taking a union of their labels, while ensuring that the labels contain only non-overlapping heaps.

$$W_{\mathcal{U} \bowtie \mathcal{V}} = \{w \cup w' \mid w \in W_{\mathcal{U}}, w' \in W_{\mathcal{V}}, \text{ and } [w] \text{ disjoint from } [w']\}$$

To define the transition components of $\mathcal{U} \bowtie \mathcal{V}$, we first need the auxiliary concept of transition interconnection. Given transitions $\gamma_{\mathcal{U}}$ and $\gamma_{\mathcal{V}}$ over $W_{\mathcal{U}}$ and $W_{\mathcal{V}}$, respectively, the interconnection $\gamma_1 \bowtie \gamma_2$ is a transition on $W_{\mathcal{U} \bowtie \mathcal{V}}$ which behaves as $\gamma_{\mathcal{U}}$ (resp. $\gamma_{\mathcal{V}}$) on

the part of the states labeled by \mathcal{U} (resp. \mathcal{V}).

$$\gamma_1 \bowtie \gamma_2 = \left\{ (w_1 \cup w_2, w'_1 \cup w'_2) \mid \begin{array}{l} (w_i, w'_i) \in \gamma_i, w_1 \cup w_2, w'_1 \cup w'_2 \\ w'_2 \in W_{\mathcal{U} \bowtie \mathcal{V}} \end{array} \right\}.$$

The internal transition of $\mathcal{U} \bowtie \mathcal{V}$ is defined as follows, where $\text{id}_{\mathcal{U}}$ is the diagonal of $W_{\mathcal{U}}$.

$$I_{\mathcal{U} \bowtie \mathcal{V}} = \{ \iota_{\mathcal{U}} \bowtie \text{id}_{\mathcal{V}} \} \cup \{ \text{id}_{\mathcal{U}} \bowtie \iota_{\mathcal{V}} \} \cup \\ \bigcup h, (\alpha_{\mathcal{U}}, \rho_{\mathcal{U}}) \in E_{\mathcal{U}}, (\alpha_{\mathcal{V}}, \rho_{\mathcal{V}}) \in E_{\mathcal{V}} (\alpha_{\mathcal{U}} h \bowtie \rho_{\mathcal{V}} h) \cup (\alpha_{\mathcal{V}} h \bowtie \rho_{\mathcal{U}} h)$$

Thus, $\mathcal{U} \bowtie \mathcal{V}$ steps internally whenever \mathcal{U} steps and \mathcal{V} stays idle, or when \mathcal{V} steps and \mathcal{U} stays idle, or when there exists a heap h which \mathcal{U} and \mathcal{V} exchange ownership over by synchronizing their external transitions.

Example B.1. We have already presented the transitions $\alpha_{\mathcal{P}}$ of \mathcal{P} and $\rho_{\mathcal{L}}$ of $\mathcal{L}_{\text{lk}, \text{lk}, \text{Inv}}$ in Sections B.1 and B.2.

The following display (40) presents the interconnection $\alpha_{\mathcal{P}} h \bowtie \rho_{\mathcal{L}} h$, which moves h from $\mathcal{L}_{\text{lk}, \text{lk}, \text{Inv}}$ to \mathcal{P} , and is part of the definition of $I_{\mathcal{P} \bowtie \mathcal{L}_{\text{lk}, \text{lk}, \text{Inv}}}$. The latter further allows moving h in the opposite direction ($\alpha_{\mathcal{L}} h \bowtie \rho_{\mathcal{P}} h$), independent stepping of \mathcal{P} ($\iota_{\mathcal{P}} \bowtie \text{id}_{\mathcal{L}}$) and of $\mathcal{L}_{\text{lk}, \text{lk}, \text{Inv}}$ ($\text{id}_{\mathcal{P}} \bowtie \text{id}_{\mathcal{L}}$).

$$\begin{array}{l} \text{pv} \xrightarrow{s} h_5 \quad * (\text{lk} \xrightarrow{s} (\text{Own}, g_5) \wedge \text{lk} \xrightarrow{j} ((\text{lk} \mapsto \text{false}) \cup h)) \rightsquigarrow \\ \text{pv} \xrightarrow{s} (h_5 \cup h) * (\text{lk} \xrightarrow{s} (\text{Own}, g_5) \wedge \text{lk} \xrightarrow{j} (\text{lk} \mapsto \text{true})) \end{array} \quad (40)$$

The external transitions of $\mathcal{U} \bowtie \mathcal{V}$ are those of \mathcal{U} , framed wrt. the labels of \mathcal{V} .

$$E_{\mathcal{U} \bowtie \mathcal{V}} = \{ (\lambda h. (\alpha_{\mathcal{U}} h) \bowtie \text{id}_{\mathcal{V}}, \lambda h. (\rho_{\mathcal{U}} h) \bowtie \text{id}_{\mathcal{V}}) \mid (\alpha_{\mathcal{U}}, \rho_{\mathcal{U}}) \in E_{\mathcal{U}} \}$$

We note that $E_{\mathcal{U} \bowtie \mathcal{V}}$ somewhat arbitrarily chooses to frame on the transitions of \mathcal{U} rather than those of \mathcal{V} . In this sense, the definition interconnects the external transitions of \mathcal{U} and \mathcal{V} , but it keeps those of \mathcal{U} “open” in the entanglement, while it “shuts down” those of \mathcal{V} . The notation $\mathcal{U} \bowtie \mathcal{V}$ is meant to symbolize this asymmetry. The asymmetry is important for our example of encoding CSL resources, as it enables us to iterate the (non-associative) addition of new resources as $((\mathcal{P} \bowtie \mathcal{L}_{\text{lk}_1, \text{lk}_1, \text{Inv}_1}) \bowtie \mathcal{L}_{\text{lk}_2, \text{lk}_2, \text{Inv}_2}) \bowtie \dots$ while keeping the external transitions of \mathcal{P} open to exchange heaps with new resources.

Clearly, many ways exist to interconnect transitions of two concurroids and select which transitions to keep open. In our implementation, we have identified several operators implementing common interconnection choices, and proved a number of equations and properties about them (e.g., all of them validate an instance of the INJECT rule).

Lemma B.1. $\mathcal{U} \bowtie \mathcal{V}$ is a concurroid.

We can also reorder the iterated addition of lock concurroids.

Lemma B.2 (Exchange law). $(\mathcal{U} \bowtie \mathcal{V}) \bowtie \mathcal{W} = (\mathcal{U} \bowtie \mathcal{W}) \bowtie \mathcal{V}$.

B.4 The empty concurroid

We close the section with the definition of the *empty* concurroid \mathcal{E} which is the right unit of the entanglement operator \bowtie . \mathcal{E} is defined as $\mathcal{E} = (\emptyset, W_{\mathcal{E}}, \{\text{id}\}, \emptyset)$, where $W_{\mathcal{E}}$ contains only the empty state (i.e., the state with no labels).

C. Atomic actions

A concurroid \mathcal{U} ’s transitions, described in Section B, specify all possible “degrees of freedom” along which a state (auxiliary or real) governed by \mathcal{U} can evolve. To tie these specifications to actual programming primitives (i.e., machine commands like *read*, *write*, *skip* or various *read-modify-write* operations), FCSL introduces a notion of an *atomic action*.

An atomic action is a 4-tuple $a = (\mathcal{U}, A, \sigma, \mu)$, where (1) \mathcal{U} is a concurroid, whose *internal* transitions an action respects; (2) A is a return type of the action; (3) σ describes states of \mathcal{U} , which a can be run from; and (4) the μ relates the initial and final states, and the result *res* of the action. FCSL imposes a soft requirement that, if all ghost information is erased from an action’s definition (e.g., manipulating with histories), it becomes operationally equivalent to a mere heap-manipulating machine command.

Definition C.1 (Action erasure). Given an atomic action a , the erasures $\lfloor \sigma \rfloor$ and $\lfloor \mu \rfloor$ of a ’s safety predicate and stepping relation are relations on heaps defined as follows.

$$\begin{array}{ll} \lfloor w \rfloor \in \lfloor \sigma \rfloor & \iff w \in \sigma \\ (\lfloor w \rfloor, \lfloor w' \rfloor, r) \in \lfloor \mu \rfloor & \iff (w, w', r) \in \mu \end{array}$$

An *atomic* is a triple $\alpha = (A, \sigma, \mu)$. It’s a special kind of actions, but over concrete heaps, rather than over states. States differ from heaps in that they are decorated with additional information such as auxiliary state and partitioning between *self*, *joint* and *other*. As with actions, A is the return type, σ is the safety predicate and μ is the stepping relation, but they all range over heaps.

We consider four different (parametrized classes of) atomics, corresponding to the four (parametrized) primitive memory operations that we consider.

Definition C.2 (Primitive atomic actions).

$$\begin{array}{ll} \text{Read}_x^A & = (A, (x \mapsto_A -) \cup h, (x \mapsto v) \cup h \rightsquigarrow (x \mapsto v) \cup h \wedge \text{res} = v) \\ \text{Write } x \ v & = (\text{unit}, (x \mapsto -) \cup h, (x \mapsto -) \cup h \rightsquigarrow (x \mapsto v) \cup h) \\ \text{Skip} & = (\text{unit}, h, h \rightsquigarrow h) \\ \text{RMW}_{x \ f \ g}^{A \ B} & = (B, (x \mapsto_A -) \cup h, (x \mapsto v) \cup h \rightsquigarrow \\ & \quad (x \mapsto f(v)) \cup h \wedge \text{res} = g(v)) \end{array}$$

The last class $\text{RMW}_{x \ f \ g}^{A \ B}$ corresponds to the family of *Read-Modify-Write* operations: they all atomically replace the current register value v with $f(v)$ for some pure function f , and return the result according to the function g [15, §5.6]. One particular representative of this family is the CAS operation, which instantiates the parameters of RMW as follows:

$$\begin{array}{ll} \text{CAS}_A \ x \ v_1 \ v_2 & \hat{=} \text{RMW}_{x \ f(v_1, v_2) \ g(v_1, v_2)}^{A \ \text{bool}}, \text{ where} \\ f(v_1, v_2)(v) & = \text{if } (v = v_1) \text{ then } v_2 \text{ else } v_1 \\ g(v_1, v_2)(v) & = (v = v_1) \end{array}$$

Definition C.3 (Operational actions). An action a is *operational* if its erasure corresponds to one of the atomics, i.e., if there exists $b \in \{\text{Read}_x^A, \text{Write } x \ v, \text{Skip}, \text{RMW}_{x \ f \ g}^{A \ B}\}$ such that

$$\lfloor \sigma_a \rfloor \subseteq \sigma_b \wedge \forall h \in \lfloor \sigma_a \rfloor \ h' \ r. (h, h', r) \in \lfloor \mu_a \rfloor \implies (h, h', r) \in \mu_b$$

In our examples we only considered operational actions, though the inference rules and the implementation in Coq don’t currently enforce this requirement (the operability of actions in the examples has been proved by hand).

C.1 Properties of atomic actions

Let $\mathcal{U} = (L, W, I, E)$. The action $a = (\mathcal{U}, A, \sigma, \mu)$ is required to satisfy the following properties.

$$\begin{array}{c}
\frac{\Gamma \vdash \{p\} c_1 : B \{q\} @ \mathcal{U} \quad \Gamma, x : B \vdash \llbracket x/\text{res} \rrbracket q c_2 : A \{r\} @ \mathcal{U} \quad x \notin \text{FV}(r)}{\Gamma \vdash \{p\} x \leftarrow c_1; c_2 : A \{r\} @ \mathcal{U}} \text{SEQ} \quad \frac{\Gamma \vdash \{p_1\} c_1 : A_1 \{q_1\} @ \mathcal{U} \quad \Gamma \vdash \{p_2\} c_2 : A_2 \{q_2\} @ \mathcal{U}}{\Gamma \vdash \{p_1 \otimes p_2\} c_1 \parallel c_2 : A_1 \times A_2 \llbracket \pi_1 \text{res}/\text{res} \rrbracket q_1 \otimes \llbracket \pi_2 \text{res}/\text{res} \rrbracket q_2 @ \mathcal{U}} \text{PAR} \\
\\
\frac{\forall x:B. \{p\} f(x) : A \{q\} @ \mathcal{U} \in \Gamma}{\Gamma \vdash \forall x:B. \{p\} f(x) : A \{q\} @ \mathcal{U}} \text{HYP} \quad \frac{\Gamma \vdash \{p_1\} c : A \{q_1\} @ \mathcal{U} \quad \Gamma \vdash (p_1, q_1) \sqsubseteq (p_2, q_2)}{\Gamma \vdash \{p_2\} c : A \{q_2\} @ \mathcal{U}} \text{CONSEQ} \quad \frac{\Gamma \vdash \{p\} c : A \{q\} @ \mathcal{U} \quad r \text{ stable under } \mathcal{U}}{\Gamma \vdash \{p \otimes r\} c : A \{q \otimes r\} @ \mathcal{U}} \text{FRAME} \\
\\
\frac{\Gamma \vdash \{e = \text{true} \wedge p\} c_1 : A \{q\} @ \mathcal{U} \quad \Gamma \vdash \{e = \text{false} \wedge p\} c_2 : A \{q\} @ \mathcal{U}}{\Gamma \vdash \{p\} \text{if } e \text{ then } c_1 \text{ else } c_2 : A \{q\} @ \mathcal{U}} \text{IF} \quad \frac{\Gamma \vdash \{p_1\} c : A \{q_1\} @ \mathcal{U} \quad \Gamma \vdash \{p_2\} c : A \{q_2\} @ \mathcal{U}}{\Gamma \vdash \{p_1 \wedge p_2\} c : A \{q_1 \wedge q_2\} @ \mathcal{U}} \text{CONJ} \\
\\
\frac{\Gamma \vdash \{p\} c : A \{q\} @ \mathcal{U} \quad \alpha \notin \text{dom } \Gamma}{\Gamma \vdash \{\exists \alpha:B. p\} c : A \{\exists \alpha:B. q\} @ \mathcal{U}} \text{EXIST} \quad \frac{\Gamma \vdash e : A \quad p \text{ stable under } \mathcal{U}}{\Gamma \vdash \{p\} \text{return } e : A \{p \wedge \text{res} = e\} @ \mathcal{U}} \text{RET} \quad \frac{\Gamma, \forall x:B. \{p\} f(x) : A \{q\} @ \mathcal{U}, x:B \vdash \{p\} c : A \{q\} @ \mathcal{U}}{\Gamma \vdash \forall x:B. \{p\} (\text{fix } f. x. c)(x) : A \{q\} @ \mathcal{U}} \text{FIX} \\
\\
\frac{\Gamma \vdash \forall x:B. \{p\} F(x) : A \{q\} @ \mathcal{U} \quad \Gamma \vdash e : B}{\Gamma \vdash \llbracket e/x \rrbracket p F(e) : A \llbracket e/x \rrbracket q @ \mathcal{U}} \text{APP} \quad \frac{\Gamma \vdash \{p\} c : A \{q\} @ \mathcal{U} \quad r \subseteq W_{\mathcal{V}} \text{ stable under } \mathcal{V}}{\Gamma \vdash \{p * r\} [c] : A \{q * r\} @ \mathcal{U} \bowtie \mathcal{V}} \text{INJECT} \\
\\
\frac{a = (\mathcal{U}, A, \sigma, \mu) \text{ is an atomic action} \quad \Gamma \vdash (\sigma \wedge \text{this } w, \lambda w'. (w, w', \text{res}) \in \mu) \sqsubseteq (p, q) \quad p, q \text{ stable under } \mathcal{U}}{\Gamma \vdash \{p\} \text{act } a : A \{q\} @ \mathcal{U}} \text{ACTION} \\
\\
\frac{\Gamma \vdash \{pv \xrightarrow{s} h * p\} c \{pv \xrightarrow{s} h' * q\} @ (\mathcal{P} \bowtie \mathcal{U}) \bowtie \mathcal{V} \quad \mathcal{P}, \mathcal{U} \text{ and } \mathcal{V} \text{ have disjoint sets of labels}}{\Gamma \vdash \{\Psi g h * (\Phi(g) \multimap p)\} \text{hide}_{\Phi, g} c \{\exists g'. \Psi g' h' * (\Phi(g') \multimap q)\} @ \mathcal{P} \bowtie \mathcal{U}} \text{HIDE} \quad \text{where } \Psi g h = \exists k: \text{heap}. pv \xrightarrow{s} h \cup k \wedge \Phi(g) \downarrow k
\end{array}$$

Figure 11. FCSL inference rules.

<i>Coherence</i>	:	$w \in \sigma \implies w \in W$
<i>Safety monotonicity</i>	:	$w \triangleright t \in \sigma \implies w \triangleleft t \in \sigma$
<i>Step safety</i>	:	$(w, w', r) \in \mu \implies w \in \sigma$
<i>Internal stepping</i>	:	$(w, w', r) \in \mu \implies (w, w') \in I$
<i>Framing</i>	:	$w \triangleright t \in \sigma \implies (w \triangleleft t, w', r) \in \mu \implies \exists w'', w' = w'' \triangleleft t \wedge (w \triangleright t, w'' \triangleright t, v) \in \mu$
<i>Erasure</i>	:	$\text{defined}(\llbracket w \rrbracket \cup h) \implies \llbracket w \rrbracket \cup h = \llbracket w' \rrbracket \cup h' \implies (w, w_1, r) \in \mu \implies (w', w'_1, r') \in \mu \implies r = r' \wedge \llbracket w \rrbracket_1 \cup h = \llbracket w'_1 \rrbracket \cup h'$
<i>Totality</i>	:	$\forall w. w \in \sigma \implies \exists w' v. (w, w', v) \in \mu$

The properties of Coherence, Step safety and Internal stepping are straightforward. Safety monotonicity states that if the action is safe in a state with a smaller *self* component (because the other component is enlarged by t), the action is also safe if we increase the *self* component by t .

Framing property says that if a steps in a state with a large *self* component $w \triangleleft t$, but is already safe to step in a state with a smaller *self* component $w \triangleright t$, then the result state and value obtained by stepping in $w \triangleleft t$ can be obtained by stepping in $w \triangleright t$, and moving t afterwards.

The Erasure property shows that the behavior of the action on the concrete input state obtained after erasing the auxiliary fields and the logical partition, doesn't depend on the erased auxiliary fields and the logical partition. In other words, if the input state have *compatible* erasures (that is, erasures which are sub-heaps of a common heap), then executing the action in the two states results in equal values, and final states that also have compatible erasures. This is a standard property proved in concurrency logics that deal with auxiliary state and code [1, 25].

The Totality property shows that an action whose safety predicate is satisfied always produces a result state and value. It doesn't loop forever, and more importantly, it doesn't crash. We will use this property of actions in the semantics of programs to establish that if the program's precondition is satisfied, then all of the approxima-

tions in the program's denotation are either done stepping, or can actually make a step (*i.e.*, they make progress).

Usually, the actions are defined in a so-called *large footprint* style. To enable writing various actions in a *small footprint* style, we also enforce the property

$$\text{Locality} : w.o = w'.o \implies (w \triangleright t, w' \triangleright t, v) \in \mu \implies (w \triangleleft t, w' \triangleleft t, v) \in \mu$$

Curiously, if the default use of the logic is in a large footprint notation, then this property is not necessary as it is not used in any proofs.

C.2 Example: pair snapshot reading and writing actions

In the pair snapshot concuroid (Section 3.2), the reading from x can be implemented by means of an atomic action

$$\text{read}X = (\mathcal{S}, (A \times \text{nat}), \sigma_{rx}, \mu_{rx}),$$

where

$$\begin{aligned}
\sigma_{rx}(w) &\triangleq w \in W_S \\
\mu_{rx}(w, w', \text{res}) &\triangleq w = w' \wedge w.j = (x \mapsto (c_x, v_x)) \cup y \mapsto - \wedge \text{res} = (c_x, v_x).
\end{aligned} \tag{41}$$

Similarly, writing into x and updating its version simultaneously is implemented via the action

$$\text{writeAndInc}X(v) = (\mathcal{S}, \text{Unit}, \sigma_{wx}, \mu_{wx}(v)),$$

such that

$$\begin{aligned}
\sigma_{wx}(w) &\triangleq w \in W_S \\
\mu_{wx}(v)(w, w', \text{res}) &\triangleq \text{res} = \text{unit} \wedge \iota_S^x(w, w')|_{c'_x} = v
\end{aligned} \tag{42}$$

where by $wr_x(w, w')|_{c'_x} = \text{res}$ we mean a restricted version of the relation induced by the transition wr_x defined in (17), such that c'_x is taken to be the action argument v , which is being written as a new value c'_x to the snapshot cell x . It is not difficult to check that $\text{read}X$ corresponds to the id transition of \mathcal{S} , whereas $\text{writeAndInc}X$ naturally corresponds to the internal transition wr_x (17).

D. Language and logic inference rules

Program specifications in FCSL take the form of Hoare 4-tuple $\{p\}c\{q\}@U$ expressing that the thread c has a precondition p , postcondition q , in a state space and under transitions defined by the concurroid U , which in FCSL plays both the role of a resource context from CSL and the role of Rely/Guarantee. The Hoare 4-tuple $\{p\}c : A\{q\}@U$ is satisfied by a command c if c 's effect is approximated by the *internal* transition of the concurroid U , c is *memory-safe* when executed from a state satisfying p , and concurrently with any environment that respects the transitions (internal and external) of U ; if c terminates, it returns a value of type A in a state satisfying q . A dedicated variable res of type A is used to name the return result in q . In FCSL, the first-order looping commands are represented by recursive procedures implemented using the fixpoint operator. In the case of recursive procedures, p and q in the procedure tuple correspond to a loop invariant, which is supposed provided by the programmer. Judgments in FCSL are formed under hypotheses from a context Γ that maps *program variables* x to their types and *procedure variables* f to their specifications. Γ is omitted in most of the examples, as it is clear from the context. The scope of logical variables is limited to the Hoare tuples in which they appear. Figure 11 lists FCSL rules.

The rule **Fix** requires proving a Hoare tuple for the procedure body, under a hypothesis that the recursive calls satisfy the same tuple. The procedure **Application** rule uses the typing judgment for expressions $\Gamma \vdash e : A$, which is the customary one from a typed λ -calculus, so we omit its rules; in our formalization in Coq, this judgment will correspond to the CiC's typing judgment.

D.1 Definition of Hoare ordering $(p_1, q_1) \sqsubseteq (p_2, q_2)$

The **ACTION** and **CONSEQ** rules use the judgment $\Gamma \vdash (p_1, q_1) \sqsubseteq (p_2, q_2)$, which generalizes the customary side conditions $p_2 \Rightarrow p_1$ for strengthening the precondition and $q_1 \Rightarrow q_2$ for weakening the postcondition, to deal with the local scope of logical variables

The generalization is required in FCSL because of the local scope of logical variable. In first order Hoare logics, the logical variables have global scope, so the above implications over p_1, p_2 and q_1, q_2 suffice. In FCSL, the logical variables have scope locally over Hoare triples, and this scope has to be reflected in the semantic definition of \sqsubseteq by introducing quantifiers.

$$(p_1, q_1) \sqsubseteq (p_2, q_2) \iff \forall w w'. (w \models \exists \bar{v}_2. p_2 \Rightarrow w \models \exists \bar{v}_1. p_1) \wedge ((\forall \bar{v}_1 \text{ res}. w \models p_1 \Rightarrow w' \models q_1) \Rightarrow (\forall \bar{v}_2 \text{ res}. w \models p_2 \Rightarrow w' \models q_2))$$

where $\bar{v}_i = \text{FLV}(p_i, q_i)$ are the free logical variables. The definition makes it apparent that the Hoare triple $\{p\}c\{q\}@U$ is essentially a syntactic sugar for a different kind of Hoare triple, which may be written as:

$$\{w. \exists \bar{v}. w \models p\}c\{\text{res } w w'. \forall \bar{v}. w \models p \Rightarrow w' \models q\}@U$$

where $\bar{v} = \text{FLV}(p, q)$. In this alternative Hoare triple, the postconditions are predicates ranging over input and output states w and w' (they are thus called binary postconditions). The advantage of the alternative Hoare triple is that the logical variables are explicitly bound, making their scoping explicit. In our Coq implementation we use this alternative formulation of Hoare triples.

D.2 Turning atomic actions into commands

Since all pre- and postconditions in FCSL are stable under the interference of the corresponding concurroid, the use of an atomic action requires explicit stabilization of its specification μ , as captured by the rule **ACTION**. This rule has been implicitly used in most

of the examples in the paper body in order to obtain stable specifications for methods like `readX` (7), `tryCollect` (34) *etc.*

To demonstrate the use of the **ACTION** rule, let us consider one of the most commonly used commands: writing into a privately owned heap, to which we gave the spec (22). As one may expect, such command “lives” in a concurroid of private heaps \mathcal{P} , supported by its internal transition $\iota_{\mathcal{P}}$, and has the following obviously stable specification (given in a *large footprint* with explicit universally-quantified *self-owned* heap h_5):

$$\{pv \mapsto^s (x \mapsto -) \cup h_5\} \text{write}(x, e) \{pv \mapsto^s (x \mapsto e) \cup h_5\} @ \mathcal{P} \quad (43)$$

The specification (22), used in the paper body, can be obtained from (43) by taking $h_5 = \text{empty}$.

Another example of a command obtained from an atomic action a method for reading from \mathcal{S} 's pointer x from Section 2. It is easy to make sure that the spec (7), which was used for verification of the `readPair` procedure, can be obtained by stabilization of the assertions defining μ_{rx} (41) of the corresponding atomic action `readX` in Section C.2.

D.3 Properties of Φ functions from the hiding rule

The abstraction function Φ is a user-specified annotation on the `hide` command (see rule **HIDE** in Figure 11 or display (19)). It maps values $g : \mathbb{U}$ (where \mathbb{U} is a user-specified PCM) to assertions, that is, predicates over states (equivalently, sets of states) of a concurroid \mathcal{V} . For the soundness of the hiding rule, Φ is required to satisfy the following properties.

$$\text{Coherence} : w \in \Phi(g) \Rightarrow w \in W_{\mathcal{V}}$$

$$\text{Injectivity} : w \in \Phi(g_1) \Rightarrow w \in \Phi(g_2) \Rightarrow g_1 = g_2$$

$$\text{Surjectivity} : w_1 \in \Phi(g_1) \Rightarrow w_2 \in W_{\mathcal{W}} \Rightarrow w_1.o = w_2.o \Rightarrow \exists g_2. w_2 \in \Phi(g_2)$$

$$\text{Guarantee} : w_1 \in \Phi(g_1) \Rightarrow w_2 \in \Phi(g_2) \Rightarrow w_1.o = w_2.o$$

$$\text{Precision} : w_1 \in \Phi(g) \Rightarrow w_2 \in \Phi(g) \Rightarrow [w_1] \cup h_1 = [w_2] \cup h_2 \Rightarrow w_1 = w_2$$

Coherence and Injectivity are obvious. Surjectivity states that for every state w_2 of the concurroid \mathcal{W} one can find an image g , under the condition that the *other* component of w_2 is well-formed according to Φ (typically, that the *other* component is equal to the unit of the PCM-map monoid for \mathcal{W}). Guarantee formalizes that environment of `hide` can't interfere on \mathcal{V} , as \mathcal{V} is installed locally. Thus, whatever the environment does, it can't influence the *other* component of the states w described by Φ .

Precision is a technical property common to separation-style logics, though here it has a somewhat different flavor. Precision ensures that for every value g , $\Phi(g)$ precisely describes the underlying heaps of its circumscribed states; that is, each state $\Phi(g)$ is uniquely determined by its heap erasure.
